Surgical Management of Differences of Sexual Differentiation and Cloacal and Anorectal Malformations

Richard C. Rink MD, FAAP, FACS

The surgical management of disorders of sex development (DSDs), genital atypia, and cloacal anomalies is one of the most complex problems a pediatric urologist/surgeon will ever encounter. The vast majority of children with DSDs will be noted to have some genital ambiguity. Surgery in this group is not only one of the most controversial topic addressed in this entire textbook but is the most controversial and debated topics in all of medicine. Even the term *DSD* is controversial. The majority of congenital adrenal hyperplasia (CAH) patients and parents were found to be dissatisfied with the term *DSD* (Lin-Su et al., 2015). The complexity of this topic has led to featured presentations by nearly every major television and print media outlet. Having a child born with a DSD is very stressful for the parents, and it is therefore imperative to create a supportive medical team that can not only help the family understand the diagnosis but also help them understand all controversies and options they have for medical and surgical management. Most families have historically opted for early surgery to “normalize” their child's genitalia. The thought of “doing nothing” for their child with DSD has been noted to be stressful for families (Creighton et al., 2012). Most parents viewed surgery as obvious and necessary and something that did not involve decision making (Crissman et al., 2011). However, Lloyd et al. (2005) and Akbiyik and Kutlu (2010) have now shown tremendous variability in genital proportions of “normal” adults and children who do not have a DSD. The family should also be informed of the possible long-term psychosocial experience of the child with DSD (Krishnan and Wisniewski, 2014). What is clear is that the parents must be made aware of all pros and cons of having surgery and also of not having surgery. **No parent or child should ever be talked into having surgery.** Regardless of whether surgery or observation is elected, the multidisciplinary family-centered medical team should be supportive of the family and should make sure the parents are aware of the options for management and the advantages and disadvantages for each option. Parents should also be made aware of and have access to support groups such as the CARES Foundation (www.caresfoundation.org), Accord Alliance (accordalliance.org), Magic Foundation (magicfoundation.org), and InterACT (interactadvocates.org).

It is not so much the technical aspects of the surgery that are controversial but rather the timing of surgical management and who has the right to decide whether surgery is appropriate; the parents or the child. As pediatric urologists, we are neither for nor against surgery but for a multidisciplinary family-centered team approach to the care of each individual child in concert with the parents/family. The reader, however, must understand that the purpose of this chapter is to address the surgical options available to the patient/parents regardless of the patient's age and to address the management of this complex spectrum of anomalies with the assumption that the parents, family, and multidisciplinary team all agree on the appropriate management plan. At a minimum, the multidisciplinary team should include the patient/family, a pediatric urologist/surgeon, a pediatric endocrinologist, a geneticist, a neonatologist, a psychologist/psychiatrist, and an ethicist with the patient/family having access to all advocacy groups and, if desired, clergy.

Classification of Urogenital Sinus and Cloacal Anomalies

Because of the spectrum and complexity of urogenital sinus anomalies and the potential for other associated organ system abnormalities, evaluation and management must be meticulous. In urogenital sinus anomalies, there is a persistent communication of the vagina with the urinary tract. Communication of the vagina with the urinary tract may occur at any point from the urethral meatus to the bladder, but the majority occur within the mid- to distal portion of the urethra. The two structures join and exit on the perineum as a single common urogenital sinus channel.

A persistent urogenital sinus is **seen in four entities.** Most commonly it occurs in **genital ambiguity states,** most frequently with CAH (Fig. 49.1). It can also occur as a **pure urogenital sinus** with normal external genitalia (Fig. 49.2). In persistent **cloacal anomalies,** there is the added complexity of rectal involvement, with all three systems—genital, urinary, and intestinal—exiting as an isolated single perineal opening. **Female exstrophy** has been thought to represent a form of persistent urogenital sinus.

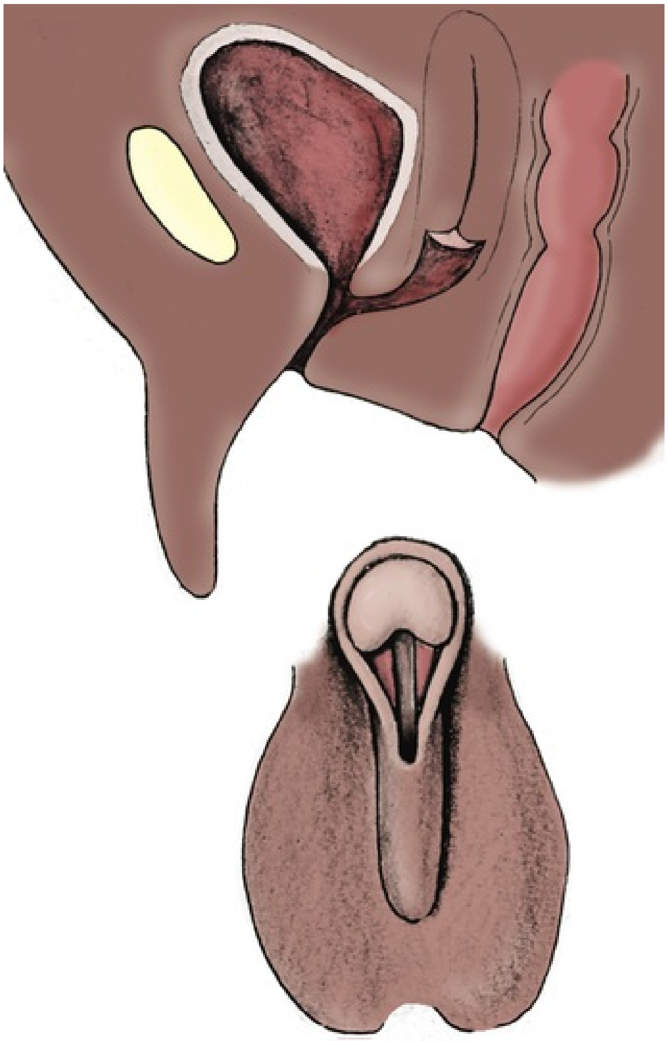

FIG. 49.1 Urogenital sinus in a patient with intersex.

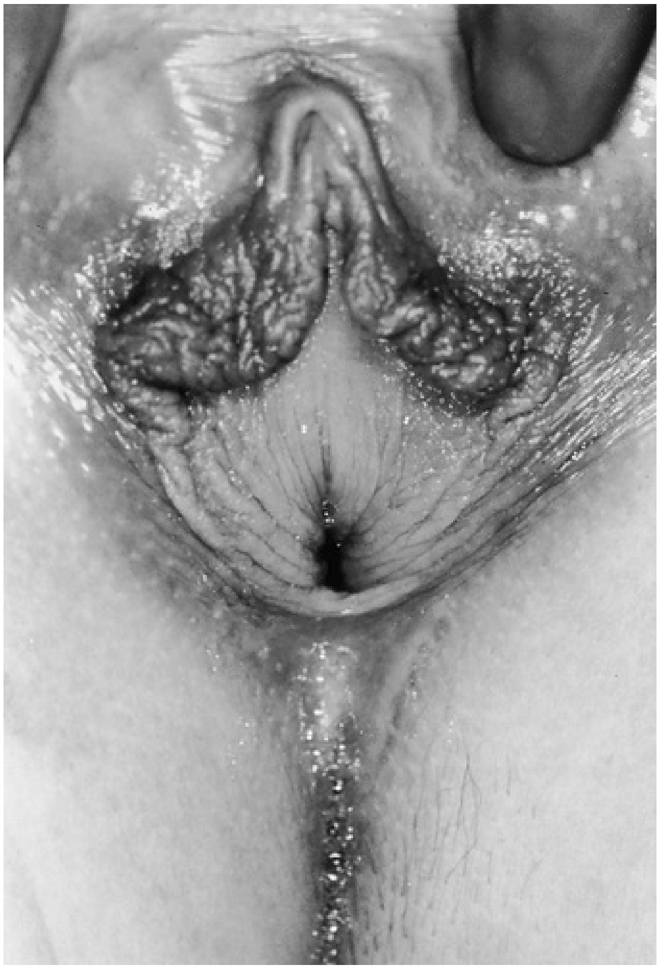

FIG. 49.2 Pure urogenital sinus abnormality.

Early descriptions of this confluence were based on previous medical training. Urologists described the vagina as entering the urethra, whereas gynecologists noted that the urethra entered the vaginal vestibule (Jones and Jones, 1954). Jaramillo et al. (1990) noted that on examination the external cloacal orifice appears vaginal in nature in some cases but in others appears more like a normal urogenital orifice (Figs. 49.3 and 49.4). **Regardless of how the confluence of the urinary and genital tracts is described, the confluence location in relation to the bladder neck is a more critical factor in surgical management than the length of the common channel** (Rink et al., 2005a).

Key Point: Urogenital Sinus Anomalies—General

- Urogenital sinus anomalies are found in four entities: genital ambiguity states, pure urogenital sinus, persistent cloaca with rectal involvement, and female exstrophy.

Evaluation

Urogenital sinus abnormalities are most often seen in DSD states, most commonly in association with CAH, which has been noted to have an incidence as high as 1 in 500 in the nonclassic, mild form (Hughes, 1988). CAH is a group of inherited autosomal recessive genetic abnormalities of which the most common enzymatic defect resulting in genital ambiguity is 21-hydroxylase deficiency. This occurs in approximately 1 in 15,000 to 16,000 persons (Merke and Bornstein, 2005; Speiser and White, 2003). Mutations in the 21-hydroxylase gene (the *CYP21A2* gene on the short arm of chromosome 6 in 90% to 95% of individuals) result in varying degrees of virilization corresponding to the type of mutation. CAH should be regarded as a spectrum disorder from mild anomalies to those with deep impact on life (Elmasri et al., 2018; Nordenskjöld et al., 2008). Therefore, initial management must focus on making an accurate diagnosis to allow proper management. Every effort should be made to establish the karyotype within 48 hours. Children with CAH require careful monitoring of fluid and electrolytes because 67% to 75% will have significant salt wasting resulting from lack of aldosterone secretion (Merke and Bornstein, 2005; Speiser and White, 2003). The classic findings of salt wasting in 21-hydroxylase deficiency are hyponatremia, hyperkalemia, high urinary sodium, low serum and urinary aldosterone, and elevated plasma renin activity (New et al., 2014). This may lead to dehydration, poor feeding, hypotension, and even vascular collapse, shock, and death (adrenal crisis). Evaluation should include rapid karyotyping of cultured peripheral leukocytes, measurement of serum electrolyte levels, and determination of hormonal levels for CAH. All results are shared with the multidisciplinary DSD team and patient/family as described earlier. There is a growing understanding of gender fluidity, not a simple binary male-female system. The child should not be named until the evaluation is complete and the family has met with the multidisciplinary team (Rink and Adams, 1998).

Cloacal anomalies are a much more complex problem involving multiple organ systems, but fortunately they occur in only 1 in 20,000 to 50,000 patients (Karlin et al., 1989; Rintala, 2016). They are the most challenging of the anorectal malformations (ARMs) and make up 13.6% of this group (Fleming et al., 1986). These children have a very broad spectrum of findings on examination of the external genitalia. Some may have a prominent phallic structure and also initially require evaluation for a DSD.

History and Physical Examination

Many children with urogenital sinus abnormalities are now identified by antenatal ultrasonography, with the findings of fluid-filled pelvic structures (vagina and bladder) with indeterminate genitalia. Furthermore, since 2009 newborn CAH screening programs have been carried out in all 50 states and in areas worldwide, which helps identify some affected children (New et al., 2014). However, the history and the physical examination remain extremely helpful in cases of genital ambiguity and can often lead to the diagnosis itself. It is critical to determine whether the mother ingested any medications during pregnancy, especially androgenic substances. A family history of early infant death or fluid and electrolyte abnormalities suggests CAH. Have other children had genital atypia or gender dysphoria? Notation should be made of any family members with abnormal pubertal development.

The physical examination can at times be very useful in determining the appropriate management and in helping to identify other organ systems involved. A general evaluation of the child's overall health should be completed before focusing on the genital examination. Abnormal facies or other physical findings suggesting a syndrome should be noted. **Hypertension can occur in children with genital ambiguity secondary to CAH from 11β-hydroxylase deficiency.** Therefore, blood pressure should be documented. Evidence of dehydration may also lead to a diagnosis of CAH. On abdominal examination, a mass, particularly a suprapubic mass, may be present because of a distended bladder, hydrometrocolpos, or both. **Hydrometrocolpos is frequently an initial sign and is often the only early finding in pure urogenital sinus abnormalities.**

In cloacal anomalies, abdominal distention may be severe secondary to hydrometrocolpos and bladder and intestinal distention. Hydrometrocolpos was noted commonly in early series (Chappell and Bleloch, 1973; Klugo et al., 1974); its incidence ranged from 29% of Peña's patients (1989) to 63% of those reported by Bartholomew and Gonzales (1978). It is caused most commonly by preferential flow of urine through the urogenital sinus into the vagina (or vaginas) with voiding and associated poor vaginal drainage. Maternal estrogen stimulation of the cervical glands results in mucus production, thereby further adding to the distention. Urine flow can occur into the rectum also. The distention of these pelvic structures has resulted in edematous, cyanotic legs, respiratory distress, and acidosis (Raffensperger, 1988).

The lower part of the back should be examined to identify any evidence of spinal cord abnormalities, which can be associated with urogenital sinus abnormalities and are very common with cloacal anomalies. Such abnormalities may take the form of a sacral dimple, hair patch, or area of abnormal pigmentation, but more commonly there is evidence of a bone abnormality, such as an abnormal buttock crease or flattened buttocks as a result of sacral agenesis.

Genital examination should note the size of the phallus and the consistency of the erectile bodies. Any degree of curvature should be documented. Huffman multiplied the width of the glans times the length of the phallus to determine the "clitoral index," which he noted should be less than 3.5 mm to be normal and was of concern when greater than 10 mm. The average clitoral length for a full-term girl in the United States was noted to be 4.0 ± 1.24 mm, and the average width was 3.32 ± 0.78 mm (Hughes et al., 2006). **Persistent isolated clitoral hypertrophy may be found in premature infants and is not associated with DSDs or other signs of ambiguity** (Williams et al., 2013). The location of the meatus of the urogenital sinus should be noted and may occur in a spectrum from a near-normal introital location to the tip of a well-formed glans. The gonads should be sought, and, when found, their number, location, and consistency should be noted. If both gonads are descended, it is extremely unlikely that a 46,XX chromosome makeup will be found. The labioscrotal folds should be examined for their relationship to the phallus and rectum, and for the degree of fusion. Increased pigmentation of the labioscrotal folds and areola may be seen in some cases of CAH as a result of increased levels of melanocyte-stimulating hormone.

In urogenital sinus anomalies, the location of the anus should be noted. Although it is usually in the normal location, anterior displacement is not uncommon, and this bridges the gap to cloacal anomalies (see Fig. 49.3). A gentle rectal examination is helpful in identifying a cervix.

Examination of a child with a persistent cloaca deserves special mention. There is a single perineal orifice because the rectum also enters this common channel. The appearance of the external genitalia assumes a much wider spectrum, from a nearly normal female appearance to much more bizarre appearances such as complete genital transposition or a blank-appearing (doll-like) perineum (Fig. 49.5) (Hendren, 1989). In some instances, there is an enlarged phallic structure that gives the genitalia an ambiguous appearance. The single perineal opening may exit what appears to be a normal vaginal introitus, or it may extend to the tip of a phallic structure. I and others have encountered children with a secondary accessory channel that exits the tip of the phallus (Hendren, 1989; Karlin et al., 1989; Krstic et al., 2001; Rink et al., 2005b).

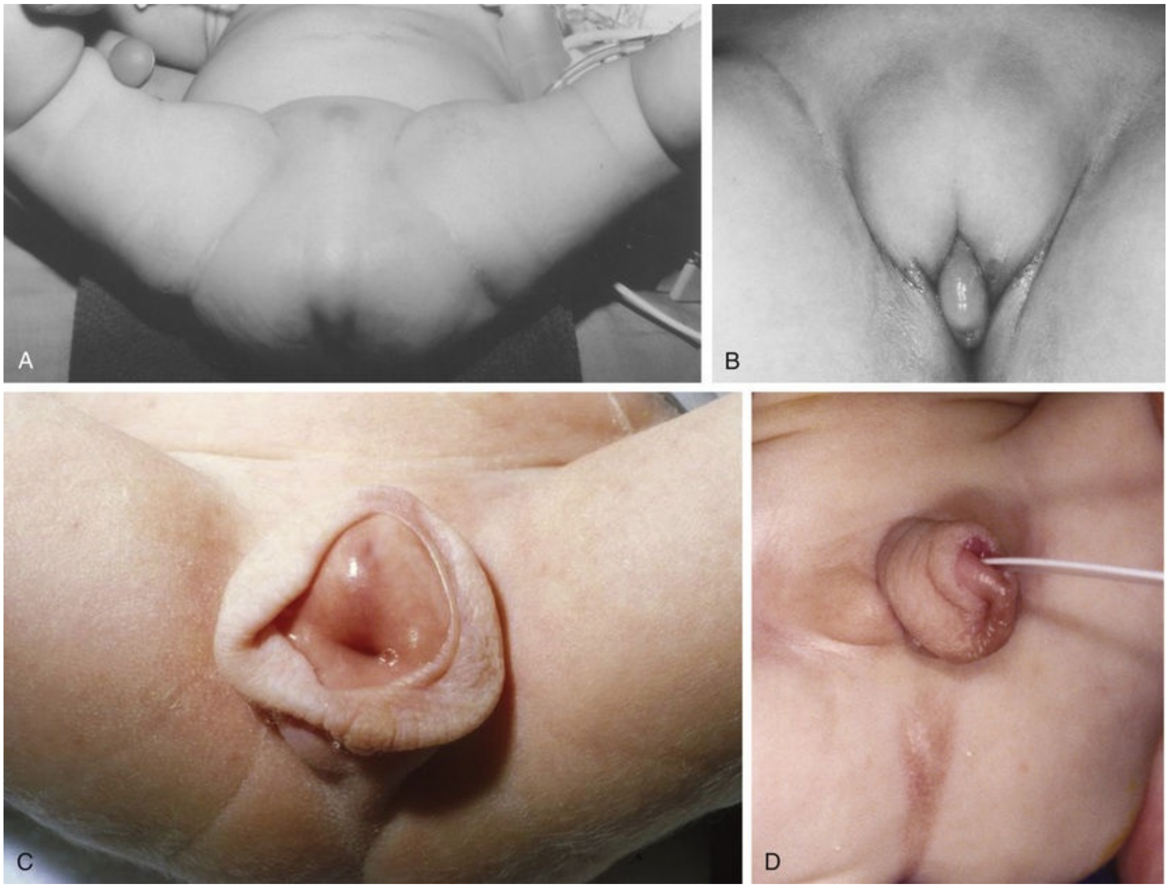

FIG. 49.5 (A) Cloaca with a blank perineal appearance. (B) Cloaca with genital transposition. (C) Cloaca, vaginal type, external appearance. (D) Cloaca, urethral type, external appearance.

Cloacal anomalies are associated with a high incidence of related anomalies in other organ systems. I have previously found 14 of 23 patients with renal anomalies, including 6 with solitary kidneys, 4 with renal dysplasia, 2 with ureteropelvic junction obstruction, 1 with duplication, and 1 with crossed fused ectopia; there were also 2 with bladder duplications (Rink et al., 2005b). Approximately 60% have some degree of septation of the vagina and uterus

(Pradhan et al., 2018; Warne et al., 2003). Kay and Tank (1977) reported that 13% of patients with cloacal anomalies have cardiovascular abnormalities, 10% have central nervous system problems, and 5% have respiratory abnormalities; vertebral, particularly sacral, anomalies are common. Many have the VACTERL association (*V*ertebral abnormalities, *A*nal atresia, *C*ardiac abnormalities, *T*racheoesophageal fistula and/or *E*sophageal atresia, *R*enal agenesis and dysplasia, and *L*imb defects), so tracheoesophageal fistula is often present (Hendren, 1986, 1988). Other gastrointestinal anomalies have been noted, including duodenal atresia and rectal duplication in 2% (Karlin et al., 1989). Gut malrotation in patients with ARM has the same frequency as in the general population, but it is more common in severe malformations. Surgeons treating these patients should address the malrotation at the time of colostomy opening if detected. The appendix should be preserved for potential future use as an appendicocecostomy for antegrade administration of enemas.

Key Points: Urogenital Sinus Anomalies—Evaluation

- Key points of the history and physical examination are findings of a family history of sudden infant death, fluid and electrolyte abnormalities, hypertension, suprapubic mass, lower extremity cyanosis, palpable gonads, hyperpigmentation, and number of perineal orifices.
- The level of the urethrovaginal confluence and the location of the rectum must be identified radiographically or endoscopically, with note made of their relationship to the bladder neck. Ultrasonography is mandatory to look for the uterus, ovaries, and kidneys.

Radiographic and Endoscopic Evaluation

Urogenital Sinus Abnormalities

Certain critical details of the anatomy, including the length of the common urogenital sinus, the location of the vaginal confluence and its proximity to the bladder neck, the size of the vagina and the number of vaginas, the presence of a cervix, and bladder and urethral anatomy, must be defined. This can be done radiographically or endoscopically. I believe that the location of the vagina in relation to the bladder neck is the critical issue in determining the type of surgery, and this distance is far more important than the length of the common channel (Ludwikowski and González, 2013; Rink et al., 2005a). This concept of the importance of the bladder neck to confluence (urethral length) has now been appreciated in cloacal anomalies and has resulted in a new treatment algorithm for surgical management of persistent cloaca (Wood et al., 2017). Vaginal confluence with the urinary tract in pure urogenital sinus and cloacal anomalies occurs in a continuum from the bladder to a nearly normal location in the perineum. **It is not simply "high" (proximal/suprasphincteric) or "low" (distal/infrasphincteric)** (Hendren and Crawford, 1969; Powell et al., 1995; Rink and Kaefer, 2002) (Fig. 49.6). I am in agreement with Ganesan et al. (2002) that the confluence of the urethra and vagina in CAH is fairly constant with a normal proximal urethra. This bladder neck to confluence distance is generally 1.5 to 2 cm in CAH infants. It is the distance from the vagina to the meatus that lengthens with increasing virilization, making some appear to be "very high." This latter distance is much more variable. Furthermore, this high confluence appearance is exacerbated in the more virilized urogenital sinus because there may be the appearance of a well-defined (malelike) external sphincter with a verumontanum appearance to the vaginal confluence just proximal to it, and the bony pelvis is more masculinized.

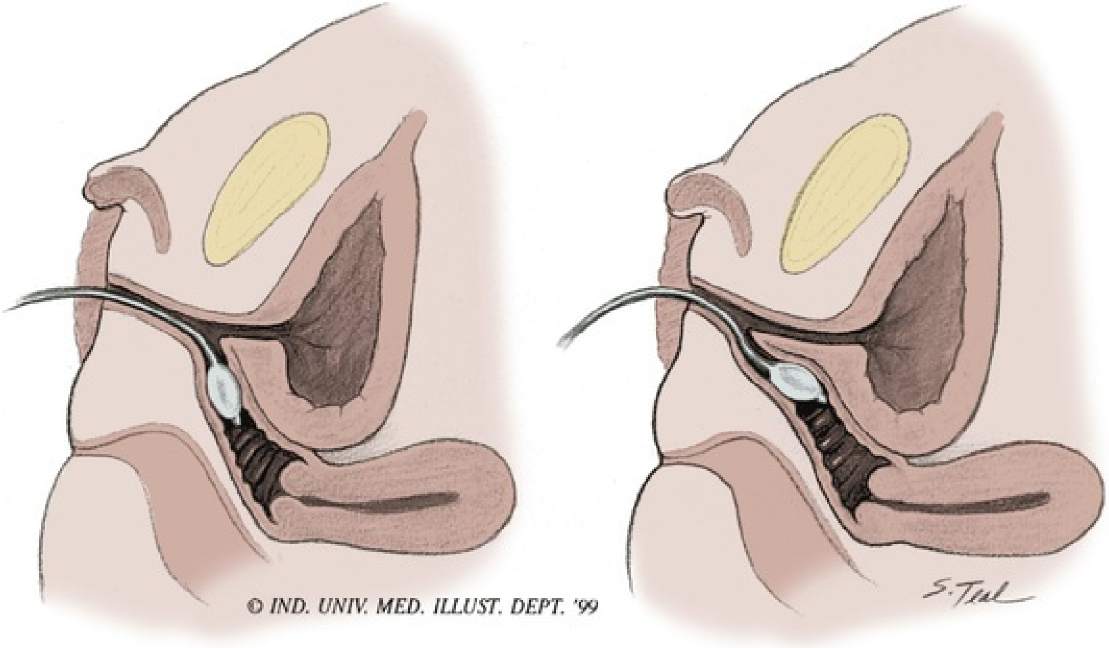

FIG. 49.6 Fogarty catheter placed in the vagina in high confluence *(left)* and in low confluence *(right)*. (© 1999, Indiana University Medical

Illustration Department.)

A urogenital sinus classification that measures the exact distance of the common channel and the distance of the bladder neck to the vagina has been devised to help delineate the exact level of the confluence and the clitoral size and appearance of the external genitalia (Rink et al., 2005a).

Ultrasonography of the urinary tract and pelvis is mandatory. The location and normalcy of the kidneys, ovaries, and uterus should be defined. Any bladder or vaginal distention should be noted. A cerebriform appearance with enlargement of the adrenal glands is indicative of CAH (Brock et al., 1998).

Filling the entire bladder, urethra, vagina, and sinus with contrast (i.e., genitography) is critical in the anatomic evaluation of many children with a urogenital sinus or cloacal anomaly (Figs. 49.7 and 49.8). Genitography is performed by placing a Foley catheter with the balloon occluding the perineal meatus and injecting a contrast agent. It is often helpful to pass a catheter into the bladder as for a voiding cystourethrogram. In some children, the vagina will only be demonstrated with voiding. A cervical impression at the vaginal dome denotes normal female internal organs. Magnetic resonance imaging (MRI) is of limited value in CAH but may be very helpful to define the anatomy in pure urogenital sinus anomalies or other DSD and cloacal conditions. In CAH patients, the internal anatomy can nearly always be defined by an endoscopy at the time of reconstruction, making genitography less useful in this group (VanderBrink et al., 2010). At our institution, the anatomy was accurately defined in CAH in only 72% of cases by genitography and it did not provide any information that could not be obtained by endoscopy, and genitography did not influence the type or timing of surgery (VanderBrink et al., 2010).

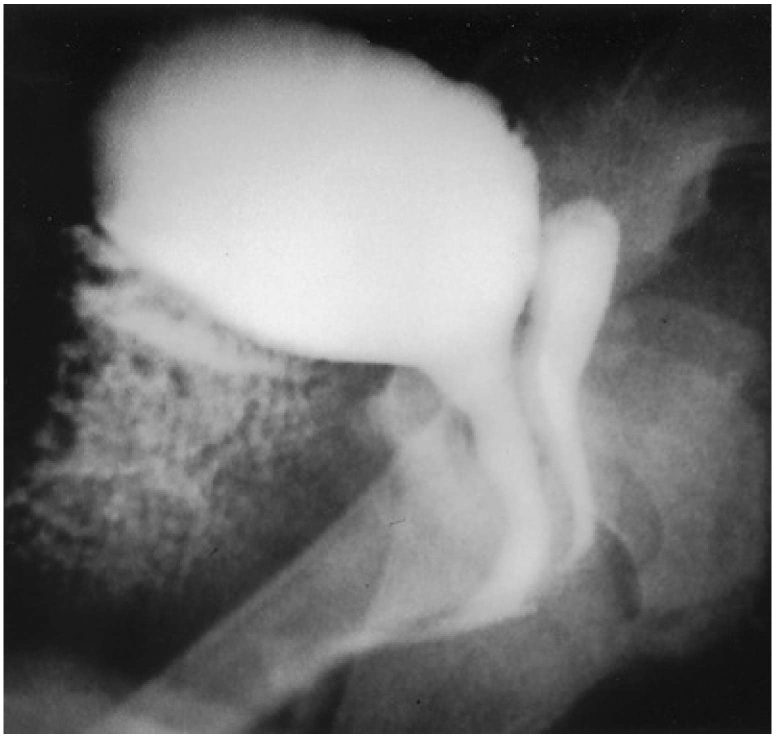

FIG. 49.7 Genitography showing low confluence of the urethra and vagina.

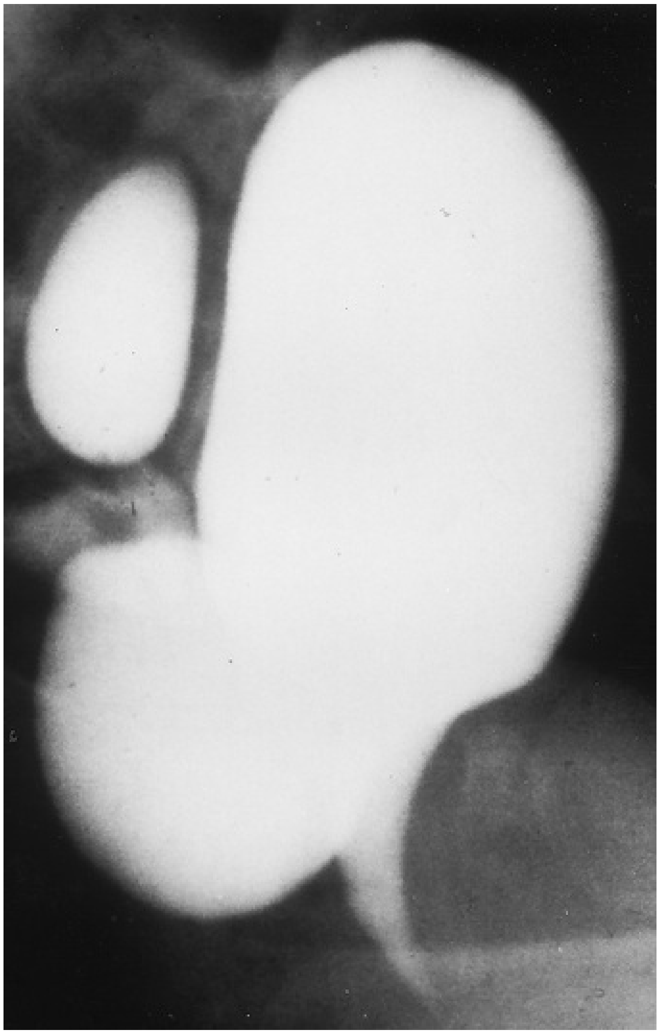

FIG. 49.8 Genitography showing high confluence of the vagina entering near the bladder neck, with flow of contrast medium into the uterus.

The most helpful diagnostic study in defining the anatomy for surgical reconstruction is endoscopy. In patients with CAH, endoscopy is usually performed at the time of reconstruction but may be necessary as a separate early procedure to help with gender identity in other DSD cases or in those with complex pure urogenital sinus anomalies or if the vagina is not identified on genitography (Rink and Kaefer, 2002). In the latter situation, multiple punctuate openings in the proximal portion of the urethra may be observed (Donahoe and Gustafson, 1994). I have found it helpful to pass a ureteral catheter into the opening and evaluate the vagina fluoroscopically in this situation (Rink and Kaefer, 2002). Again, the exact location, size, and number of the vaginas should be recorded (Fig. 49.9). Hendren has noted a malelike external sphincter in severely masculinized children, with the vagina entering proximal to it in a verumontanum-like structure (Hendren and Atala, 1995; Hendren and Crawford, 1969). In my initial experience, I thought this rarely if ever occurred (Adams and Rink, 1998), but as noted earlier, I have more recently seen several CAH children with a completely masculinized malelike urethra with an external sphincter and verumontanum-like structure.

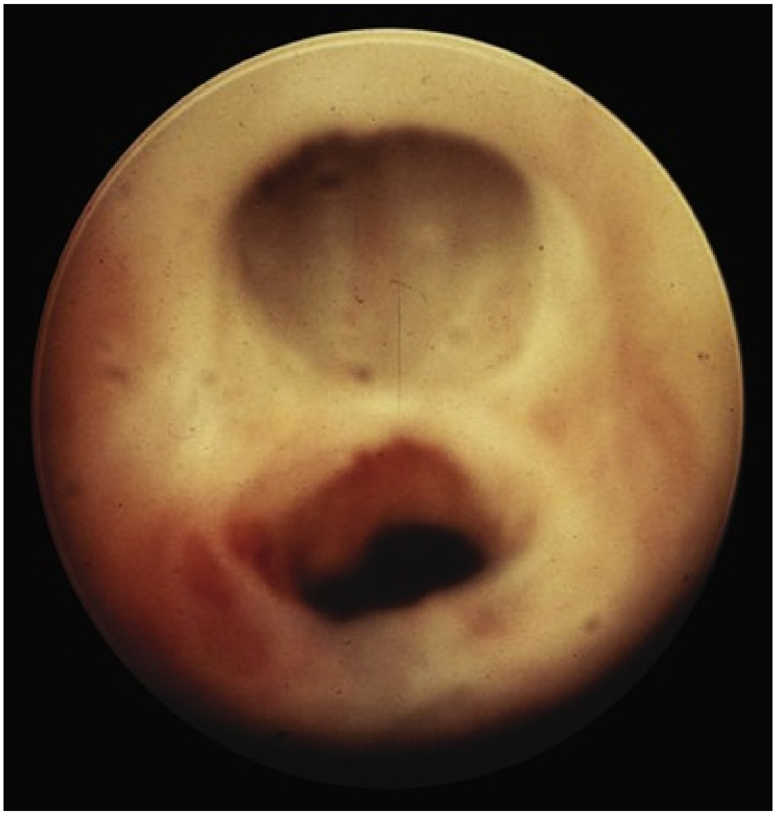

FIG. 49.9 Endoscopic view of confluence. The urethra is superior; the vagina is inferior.

Rarely, even with the evaluation described, some children with DSD require gonadal biopsy or evaluation of the internal genitalia, which has historically been done by laparotomy but in most cases can now be easily performed laparoscopically. Regardless of the means, it should be performed only when the findings would influence the gender of rearing (Rink and Adams, 1999). **If a biopsy is necessary, a deep longitudinal incision should be made in the gonad because the ovarian component of ovotestes may completely surround the testicular component or be located at the poles** (Hensle and Kennedy, 1998; Schnitzer and Donahoe, 2001). Finally, scrotal skin biopsy may at times be helpful in males with incomplete androgen insensitivity, decreased

5α-reductase activity, or decreased dihydrotestosterone binding (Griffin and Wilson, 1989). Certainly, all children with DSD should undergo chromosomal, endocrinologic, and genetic evaluation. This is well described in Chapter 48.

Cloacal Anomalies

Evaluation for cloacal anomalies begins with antenatal ultrasonography because several groups have now reported the prenatal diagnosis of persistent cloaca (Adams and Rink, 1998; Cacciaguerra et al., 1998; Cilento et al., 1994; Odibo et al., 1997; Petrikovsky et al., 1988; Shalev et al., 1986; Warne et al., 2002a). The diagnosis has been made as early as 19 weeks' gestation. **The finding of transient fetal ascites with bilobed or trilobed pelvic cystic structures, bilateral hydronephrosis, and decreased amniotic fluid is diagnostic** (Cacciaguerra et al., 1998; Warne et al., 2002b). The ascites is thought to develop via retrograde flow of urine into the uterus and out the fallopian tubes secondary to outlet obstruction from the distended vagina (Adams et al., 1998; Cacciaguerra et al., 1998).

Postnatal radiographic evaluation begins with a plain abdominal film (Jaramillo et al., 1990) **and abdominal ultrasonography.** A pelvic mass may be obvious on a kidneys, ureters, and bladder view. Retrograde flow of urine and meconium, as described earlier, may result in the classic linear calcifications or calcified meconium. More granular calcifications may be noted along the course of the rectum as a result of urine flow into the rectum that yields calcified meconium (Jaramillo et al., 1990). **Abdominal ultrasonography is very important to visualize not only the pelvic anatomy but also the kidneys because hydronephrosis is common** (Hendren, 1998). Hydronephrosis is usually related to hydrocolpos, with the distended vagina compressing the bladder neck and resulting in varying degrees of bladder outlet obstruction (Hendren, 1998). Ureteral compression may also occur; however, I have seen hydronephrosis caused by primary obstructive megaureter in patients with cloacal anomaly.

Ultrasonography may also detect other renal anomalies. **Renal anomalies such as dysplasia, fusion anomalies, ectopia, ureteropelvic junction obstruction, and duplication have been seen in 33% to 83% of children with a persistent cloaca** (Kay and Tank, 1977; Rink et al., 2005b; Warne et al., 2002a).

As opposed to some urogenital sinus abnormalities in CAH in which genitography may be avoided, both genitography and endoscopy are

mandatory to define the anatomy, which is even more complex with a cloacal anomaly.

The technique and goals of genitography and endoscopy are the same but must now include identification of the rectal and vaginal confluence. The length of the urethra and its communication with the cloaca are important for reconstructive purposes. In Hendren's patients, the urinary communication to the cloaca was urethral in 77%, but in 23% there was virtually no urethra and the communication was noted at the bladder neck level (Jaramillo et al., 1990).

Cloacal malformations may interfere with Mullerian duct fusion often leading to Mullerian anomalies (Gupta et al., 2014). Thus the vaginal anatomy may be quite complex and variable. In Hendren's report of 154 patients, 66 had one vagina, 68 had two vaginas, and the vagina was absent in 20 (Hendren, 1998). In a recent report by Pradhan et al. (2018), 63% of patients had vaginal and uterine duplications. They noted that defining this genital anatomy can be challenging, even with the use of pelvic ultrasonography, MRI, cloacogram, and vaginoscopy. They had the most success in defining the anatomy preoperatively with vaginoscopy (92%) and the least success with pelvic ultrasonography, which was accurate in only 4 of 8 (50%). In 5 of 15 patients, the cloacogram did not correlate with defined anatomy at the time of laparoscopy/laparotomy. Vaginal duplication has been seen in nearly all of my patient population (Rink and Yerkes, 2001) (Fig. 49.10). The duplication anatomy is also variable. Most authors have observed that the vaginas enter side by side with a single opening into the cloaca, but separate openings have been noted. The vaginas may be of different size, and one may enter the sidewall of the other. A cervix is usually seen at the top of each vagina. **The vaginal entrance into the cloaca again lies along a spectrum from the bladder to a location near the perineum.** Although the uterus is usually similar to the vagina (i.e., two vaginas with two uteri), the vagina may be absent with the uterus still present or the uterus may be hypoplastic. Hall et al. (1985) found a bicornuate uterus, hypoplastic uterus, or uterus didelphys in 35% of their patients with persistent cloaca.

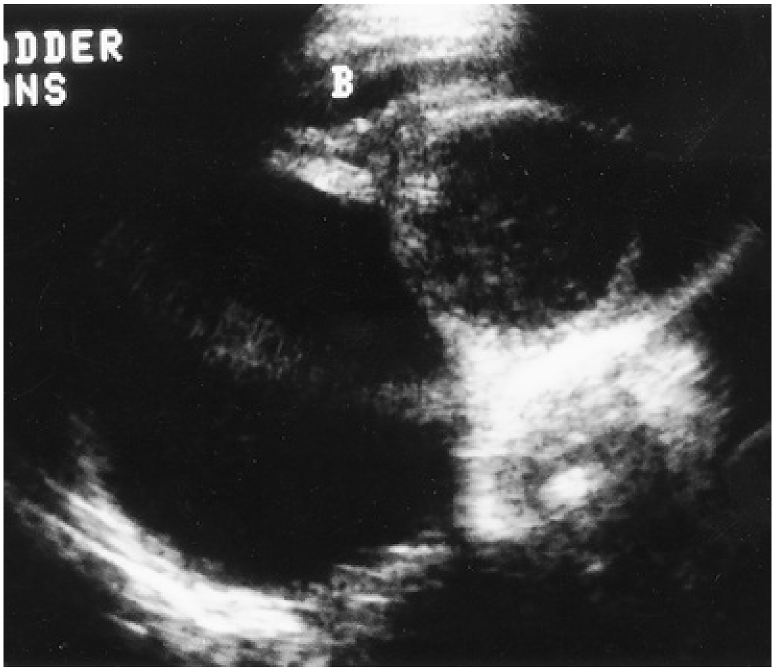

FIG. 49.10 Pelvic ultrasonography in a patient with a cloaca. Duplicate fluid-filled vaginas are seen posterior to the decompressed bladder *(B).*

The rectal confluence is equally complex, with the entrance in my experience most commonly located just at the level of the vaginal confluence. This rectal opening may be broad, or it may have a long, narrow fistulous tract. It can even enter the vagina or bladder with no communication to the common cloaca itself. The most common entrance in my experience is within the septum of a duplicated vagina, with all three joining the cloaca together (Rink and Kaefer, 2002). The rectal communication has been found to be vaginal in 68% and cloacal in 11%, with the remainder in other locations (Jaramillo et al., 1990). The length and configuration of the common cloaca should also be noted because it has important surgical and anatomic implications. At times, the common channel is narrow and appears very much like a urethra; in other instances, the channel is much larger and redundant and appears more like a vagina. The urethral appearance was found in 48% of patients and the vaginal appearance in 52% (Jaramillo et al., 1990). **I and others have noted that the urethral types result in higher outlet resistance and are more likely to lead to hydrocolpos** (Adams et al., 1998; Warne et al., 2002b).

The frequent presence of associated organ system abnormalities necessitates further radiographic evaluation. Echocardiography should always be performed. MRI is necessary for evaluating the lumbosacral spine and assessing the pelvic anatomy and musculature. Historically, it has been well recognized that sacral anomalies are common. Peña (1989) noted a normal sacrum in only 35% of his 54 patients, and Jaramillo et al. (1990) reported sacral agenesis in 40% of Hendren's 65 patients. De Filippo et al. (1999) found 10 of 21 patients with imperforate anus or cloaca to have an abnormality of the sacrum and spine. **With the use of MRI, spinal cord abnormalities have been more commonly detected, with an incidence as high as 43%** (Jaramillo et al., 1990). Hendren (1998) found that one-third of his patients had a tethered spinal cord. Skin stigmata in the lumbosacral region were absent in 8 of 10 patients with spinal cord tethering in a report by Morimoto et al. (2003). MRI has also been very helpful in defining the level of the rectal atresia and in identifying the degree of sphincteric muscle development (Sato et al., 1988).

Because of the complexity of the anatomy and the frequency of hydrometrocolpos, a child with a cloacal anomaly often needs endoscopy early as a separate procedure to decompress the vagina and bladder and to define the anatomy. As a general rule, visualization of the vagina (or vaginas) is easily accomplished, but entry into the bladder can be very difficult and even impossible at times in a neonate because it is compressed very anteriorly by the distended vagina. The vagina should always first be emptied. Identification of the rectal fistula can also be difficult at times. Once it is located, mucus and fecal material should be irrigated from the colon, which can be done by irrigation through the scope in combination with irrigation through the mucous fistula of the divided colostomy. Passage of a small catheter through the mucous fistula when present can be very help in defining the location of the rectal confluence. The length of the urethra to the vaginal and rectal confluence and the length of the common cloacal channel should be documented. The length of the common channel is helpful in cloacal patients in predicting fecal continence outcomes (Peña et al., 2004).

Surgical Reconstruction of Disorders of Sex Development and Urogenital Sinus

Initial Management, Timing, and Principles

The majority of children born with a urogenital sinus have genital ambiguity, and this should be initially evaluated by the multidisciplinary DSD team. It is extremely important that the family be made aware of all controversies surrounding the medical and surgical management of these children. Certainly, most families, physicians, and surgeons have historically made the decision to proceed with early surgical procedures to “normalize” the child to allow what was thought to be positive psychosocial adjustment (Schober, 1998). This was thought to relieve the parents’ distress and improve their outlook toward their child, although there is limited evidence for this. The thought has been that raising a child with genital ambiguity would be extremely difficult (Thomas, 2004). Creighton et al. (2012) noted that the idea of “doing nothing” can be a stressful concept for parents. Trakakis et al. (2009) stated that surgical treatment must be offered between 2 and 6 months because the tissues are maximally pliable and psychological trauma is minimized. Clearly, gender assignment when the individual's ultimate gender identity is unknown is a challenge and is at the core of this controversy (Mouriquand et al., 2014). A number of advocacy groups including InterACT, Human Rights Watch, the United Nations, three former Surgeons General, and some physician groups have questioned the wisdom of early surgery. In fact, most of these groups have supported a moratorium on surgery for genital atypia until the patients are at an age where they can express their desire for or against surgery. This exact age has yet to be defined. It is obvious that informed consent is impossible with an infant, and many believe that the decision for genital surgery is a right of the patient, not the parents. The ethical issues involving parents’ rights and responsibilities to make decisions for their child remain unresolved (Lee and Witchel, 2002). Unfortunately, the infant is the passive center of the team but ultimately has the most important voice (Yerkes and Rink, 2010). In 2002, Rangecroft noted that data on the impact of raising a child with genital ambiguity are still lacking (Rangecroft, 2002). Regardless of one's personal beliefs, all pros and cons of both surgery and observation must be presented to the parents without bias, and certainly observation with psychological and peer support must be an option (Creighton and Liao, 2004). However, this same psychological and peer support should be given to the parents who do elect to proceed with early surgical management (Rink and Szymanski, 2015).

With current operative techniques, excellent cosmetic results can be achieved with feminizing genitoplasty for the virilized female. Although anatomic appearance likely plays a role, it must be remembered that one's sexual identity is a result of many factors (Mouriquand et al., 2014). It is known that the brain is the dominant organ in sexual orientation (Woodhouse, 2004). Schober (1999) has pointed out that little is known about how adults adjust to genitoplasty, nor are there any data on what path infants undergoing genitoplasty might have chosen had the opportunity been given to them as adults. Feminizing genitoplasty is unique in that outcomes of early surgery are not known for perhaps 20 years, and the results reported at the time of this writing may be based on techniques no longer used. However, it is clear that genital surgery does not “cure” a DSD. It is known that women with CAH are less satisfied with their genitalia than control subjects whether they had undergone an operation or not (Nordenskjöld et al., 2008).

Unfortunately, a dilemma remains for DSD surgery because there is no absolute correct answer at this time. Information should **never** be withheld from the parents. Secrecy from the family or patient has no place in the care of DSD. Counseling should always be provided. At our institution, all parents meet with a clinical psychologist. Parents must be informed of all risks and options and be made aware of the current state of knowledge. They should also be given access to all major advocacy groups regardless of the group's stance on surgery. There has been a changing of attitudes regarding early reconstructive procedures particularly with regard to clitoral surgery (Lee et al., 2006). Szymanski et al. (2018) evaluated parental concerns and decision making when considering surgery in children with CAH for 16 consecutive families. The largest concerns were not surgical but on life-threatening and developmental effects of CAH and the side effects of necessary medications. One of the least prioritized issues was the child not being involved in the decision making. Our group also evaluated decisional regret (DR) in 39 CAH parents after genital surgery and noted 20.5% of parents to have some DR after genitoplasty (mild to moderate) with no parent having severe DR. This DR was less than that found in parents after hypospadias, adenotonsillectomy, or pediatric cancer treatment, and no parent preferred delayed surgery (Szymanski et al., 2017).

For the purposes of the remaining description of surgical techniques, it is assumed that all parties (parents and multidisciplinary team as described earlier) agree that surgery is warranted. The techniques described are applicable to all ages from infants to adults.

Children born with a urogenital sinus associated with genital ambiguity usually have clitoral hypertrophy, some degree of fusion and anterior displacement of the labia majora with absence of the labia minora, and a common urogenital sinus (Fig. 49.11). Furthermore, it has been shown that there is significant variability in what is considered normal clitoral, vaginal, and labial size (Akbiyik and Kutlu, 2010; Lloyd et al., 2005). **Genital reconstruction has historically addressed all of these issues and therefore has generally involved three steps: (1) clitoroplasty, (2) labioplasty, and (3) vaginoplasty.**

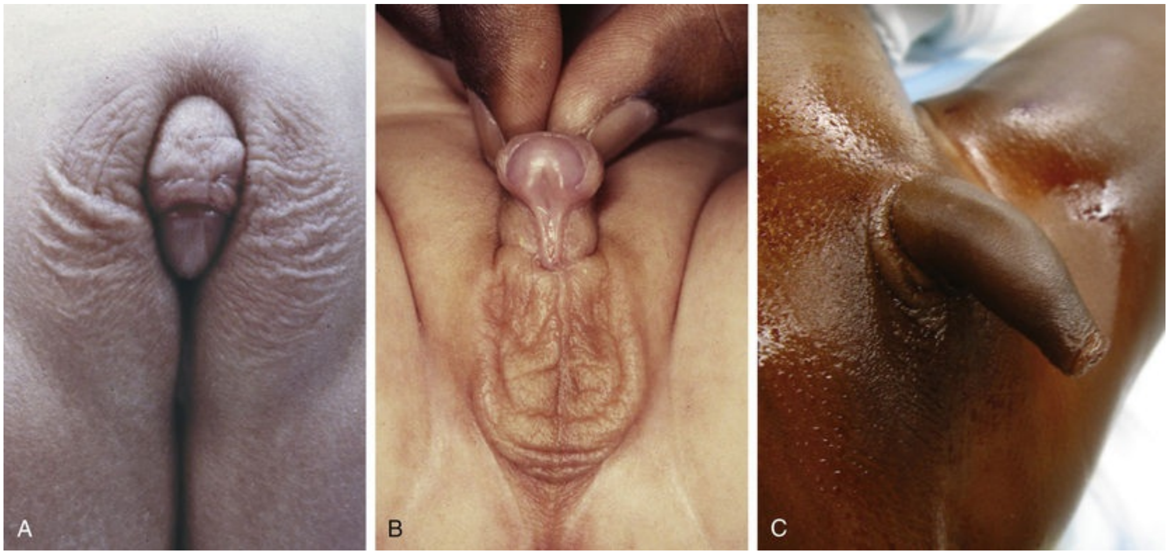

FIG. 49.11 External appearance of genitalia in congenital adrenal hyperplasia. (A) Moderately virilized with incomplete labioscrotal fusion. (B) Moderately virilized with complete labioscrotal fusion. (C) Severely virilized.

Historically, clitoroplasty has been performed early in life, but this has again been challenged by DSD advocacy groups and some physicians. In the mid-1900s, there was not thought to be an optimal timing for reconstruction (Jones and Jones, 1954; Lattimer, 1961), but more recently, clitoral reconstruction has been carried out progressively earlier. Gross et al. (1966) and Spence and Allen (1973) noted that clitoral surgery can ideally be performed when the child is 1 year of age. By the 1980s, clitoral surgery was recommended as early as the first few months of life (Snyder et al., 1983). More recently, de Jong and Boemers

(1995) reported surgical correction at 1 to 3 weeks of age. Parents are now less likely to choose surgery for minimal clitoral hypertrophy (Lee and Witchel, 2002), and a consensus document recommends surgery for only the more severe degrees of hypertrophy (Prader III to IV) (Hughes et al., 2006). In a recent review on timing, it was suggested that clitoral surgery be considered in infancy for Prader score of III or greater (Speiser et al., 2010). The most recent reports agree with early surgery for severe clitoral hypertrophy (Acimi, 2013; Braga and Salle, 2009; Escala Aguirre et al., 2009; Guarino et al., 2013; Speiser et al., 2010; Vidal et al., 2010; Willihnganz-Lawson et al., 2013). Johannsen et al. (2010) noted a higher satisfaction with clitoral function the younger the age at clitoral surgery. However, clitoral surgery, whether recession or resection, is overwhelmingly the most controversial component of the genital atypia management debate.

The optimal timing for vaginoplasty also continues to be debated. It is important to remember that the vagina serves no function in childhood. Some have based the timing partly on the level of the vaginal confluence. A consensus statement on CAH from the Lawson-Wilkins Paediatric Endocrine Society (LWPES) and the European Society for Pediatric Endocrinology (ESPE) recommends surgery in the 2- to 6-month-old range for those with a high vaginal confluence, and surgery between 12 months and adolescence is not recommended (Joint LWPES/ESPE CAH Working Group, 2002). **“There is inadequate evidence currently in relation to establishment of functional anatomy, to abandon the practice of early separation of the vagina and urethra”** (Hughes et al., 2006). In a poll of delegates at the Fourth World Congress of the International Society of Hypospadias and Disorders of Sex Development, surgery before 2 years of age was preferred by 78% of surgeons, and most suggested single-stage clitoroplasty, vaginoplasty, and labioplasty (Yankovic et al., 2013). In an effort to determine current practice in the United States, Roth et al reviewed the Pediatric Health Information System (PHIS) database, which is collaborative data collected from 43 free-standing pediatric hospitals. Using a timeframe of 2004 to 2014, they identified 4617 unique female CAH encounters with 544 undergoing surgery (Roth et al., 2018). They noted the average age of genital surgery to be 9.9 months, with 92% having vaginal surgery, 48% having clitoral surgery, and 85% having perineal surgery. Readmission for any reason was noted in 13.8%, with 4 % having an unidentified surgical complication. Several studies have noted that the overwhelming majority of CAH patients or parents are happy with their decision for early genital surgery, and those who had later surgery generally wished it had been done earlier (Binet et al., 2016; Daynor et al., 2004; Fagerholm, 2011; Marei et al., 2015; Szymanski et al., 2017; Wisniewski et al., 2004).

Simultaneous performance of clitoroplasty, vaginoplasty, and labioplasty has been the historical standard practice for a child with a low (distal) vaginal confluence. Two separate schools of thought have been put forth for a high vaginal confluence. Some believe that the high rate of vaginal stenosis warrants delay of vaginal surgery until after puberty, which also avoids any need for vaginal dilation (Alizai et al., 1999; Creighton et al., 2001; Escala Aguirre et al., 2009; Rangecroft, 2002; Snyder et al., 1983; Sotiropoulos et al., 1976; Thomas, 2004). Others have recommended that vaginoplasty for the small hypoplastic vagina (<3 cm) be delayed also (Salle et al., 2012). Others have found the incidence of vaginal stenosis to be higher in those who undergo surgery after puberty rather than during infancy (Eroglu et al., 2004). **There is some technical surgical advantage to combining vaginoplasty, regardless of the vaginal location, with clitoroplasty and labioplasty in a single-stage procedure. This allows the surgeon flexibility in using redundant phallic skin for the reconstruction, which is compromised when the skin has previously been mobilized** (de Jong and Boemers, 1995; Gonzalez and Fernandes, 1990; Hendren and Atala, 1995; Mandell et al., 1988; Passerini-Glazel, 1998; Rink et al., 1997; Vidal et al., 2010)**. Lean et al.** (2007) **found any plans for one-stage repair to give better results. Furthermore, several authors have noted that maternal estrogen stimulation of the child's genitalia results in thicker vaginal tissue that is better vascularized, thus making it easier to perform early vaginal mobilization** (Braga and Salle, 2009; de Jong and Boemers, 1995; Donahoe and Gustafson, 1994; Eroglu et al., 2004; Farkas et al., 2001; Hamza et al., 2001; Hensle and Bingham, 2002; Passerini-Glazel, 1989; Rink and Adams, 1999). Those in favor of pubertal surgery generally perform it for the high vagina and note the advantage of the patient being able to provide consent (Escala Aguirre et al., 2009; Guarino et al., 2013). As in infants, the estrogen stimulation at puberty may be advantageous. Schober (2004) has noted that estrogen has a beneficial effect on tissue healing that, along with vaginal growth and distention, may result in improved outcomes, making puberty the best opportunity for reconstruction. Still others believe that a hybrid of these two—clitoroplasty and labioplasty in infancy with vaginoplasty at puberty—is most appropriate, particularly in the setting of a high vaginal confluence (Creighton and Farhat, 2005; Escala Aguirre et al., 2009; Guarino et al., 2013). The surgery is not easier, and there is no evidence that actual healing is better at puberty (Braga and Salle, 2009). **At the time of this writing, there is no universal agreement among those caring for DSD children on optimal timing for vaginoplasty, and sadly there are no adequate data comparing early versus late surgery.**

The clitoris is a sexual organ; therefore, when performing clitoroplasty, every effort is made to not only provide excellent cosmesis but also retain normal clitoral innervation for optimal sexual gratification. Clitoral surgery has undergone significant evolution since Hugh Hampton Young's work in 1934 (Young, 1937). Initial efforts were primarily directed at not just amputating the clitoris but also completely excising all clitoral tissue to avoid any later painful erection (Gross et al., 1966; Hendren and Crawford, 1969; Jones and Jones, 1954). Clitoral amputation was based on reports by Hampson (1955) and by Money (1955), who noted that the clitoris was not necessary for normal sexual response. As recognition of the importance of the clitoris evolved, several ingenious clitoral recession techniques that preserved the innervation and all clitoral tissue were reported. Lattimer (1961) recessed the clitoris in subcutaneous fat and buried it beneath the skin. He also denuded the glans epithelium, which would not be recommended today. Kaplan (1967) reported an interesting technique of splitting the two corpora apart and performing closure in a transverse Heineke-Mikulicz fashion. Pellerin (1965) and also Randolph and Hung (1970) buried the corpora beneath the pubis. Efforts to preserve the glans based on a flap were attempted as early as the 1930s by Young, but the glans sloughed (Young, 1937). Schmid (1961) was the first to report excising corporeal tissue yet preserving the neurovascular bundle with the glans intact. Kumar et al. (1974) later noted a similar technique proposed by Kiefer the same year. Spence and Allen (1973) excised all of the clitoral shaft but left the glans intact to survive from the attached ventral urethral plate, but this technique excised all of the neurovascular bundle. **Virtually all techniques since then have been based on Schmid's preservation of the neurovascular bundle** (Barrett and Gonzales, 1980; Glassberg and Laungani, 1981; Mollard et al., 1981; Rajfer et al., 1982; Shaw, 1977). Although the glans often did well with these techniques, shrinkage and devascularization occurred at times. **Kogan et al.** (1983) **reported subtunical excision of the erectile tissue by incising laterally through the Buck fascia to resect the erectile corpus cavernosa tissue.** Clitoroplasty techniques exhibited only minor technical advances until the demonstration of the neurovascular anatomy of the clitoris by Baskin et al.

(1999). This work suggests that a ventral, rather than lateral, incision would preserve not only the main dorsal neurovascular bundle but also the neural branches that fan out laterally (Fig. 49.12). Currently, much research is under way to further evaluate clitoral neuroanatomy, and develop techniques to evaluate sexual sensitivity. I believe that the Buck fascia with its neurovascular bundle and glans should always be preserved. Pippi Salle reported a technique whereby the corporeal bodies are mobilized and disassembled and then placed in the labial fat. This has the potential option of later use for reconstruction of the phallus should the patient choose a male gender identity (Pippi Salle et al., 2007) although the results of this remain unknown.

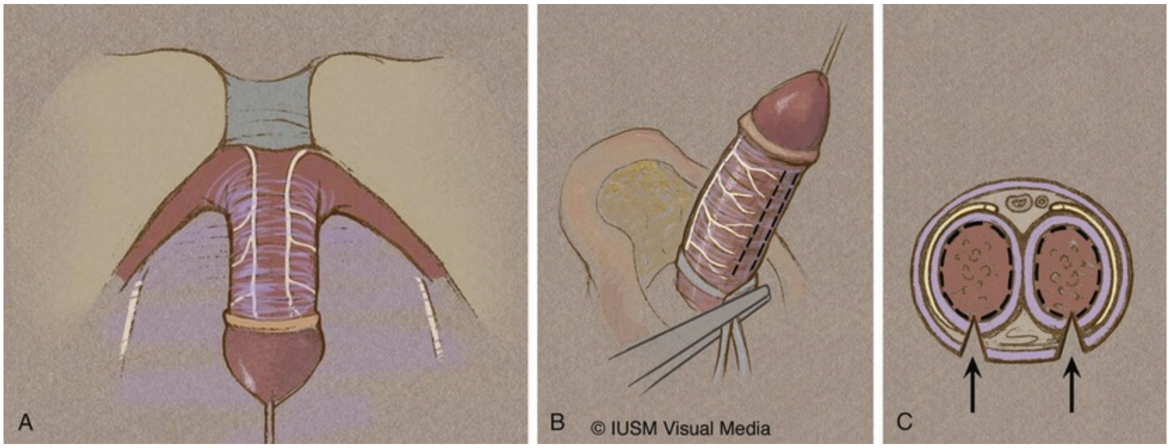

FIG. 49.12 Hypertrophied clitoris with dorsal nerves and branches. (A) Anteroposterior view. (B) Side view. (C) Cross-sectional view. (© Indiana University Medical Illustration Department.)

Vaginoplasty techniques have similarly evolved, with all repairs based on a few landmark reports. **Almost every vaginal repair today uses a posteriorly based perineal flap proposed by Lattimer and originally described by Fortunoff et al. in 1964.** This wide-based "Fortunoff flap" has been modified to a more omega-shaped flap that has resulted in improved cosmesis (Freitas-Filho et al., 2003; Jenak et al., 2001). In 1969, **Hendren and Crawford reported a "pull-through" vaginoplasty for a high vaginal confluence.** Their efforts to establish the location of the vaginal confluence as the determining factor for the type of vaginoplasty remain the basis for all vaginoplasties today. Vaginal reconstruction techniques now generally take the form of one of four types:

1. **The "cut-back" vaginoplasty is rarely used today. I and most authors**

believe it is only appropriate for simple labial fusion. However, Escala Aguirre et al. (2009) **recently reported its use in Prader I and II children.**

2. The “flap” vaginoplasty is applicable to a low (distal) vaginal confluence. In this procedure, the posterior walls of the sinus and vagina are opened, but the anterior wall of the vagina is left intact. The posterior perineal flap fits into the opened vagina. **This procedure does not change the level of confluence; it simply widely opens the introitus and urogenital sinus** (Rink and Adams, 1998). Mild degrees of female hypospadias are common with this technique. I and others believe that a flap vaginoplasty should never be used for patients with a very high vaginal confluence because it may result in a short hypospadiac urethra, vaginal voiding, infections, and even incontinence (Hendren and Atala, 1995; Rink and Adams, 1999).
3. **The “pull-through” vaginoplasty may be used for any level of confluence but is generally reserved for a very high confluence.** In this procedure, the vagina is separated from the urogenital sinus, and the sinus is used to create a urethra. The mobilized vagina may reach the perineum, but in most cases skin flaps have been required.
4. **Complete vaginal replacement can be achieved by several techniques, but this is used only for a rudimentary or absent vagina.**

Labioplasty techniques also continue to evolve. In CAH and other DSD states, the labia minora are absent and the labia majora are superior to the new vaginal introitus. Labia minora are created by using the split phallic skin as described by Marberger (1975). Both the labia majora and labia minora should be moved inferiorly by YV-plasty to create a normal cosmetic appearance of the vagina now located between the labia (Hendren and Donahoe, 1980; Rink and Adams, 1998) (Fig. 49.13).

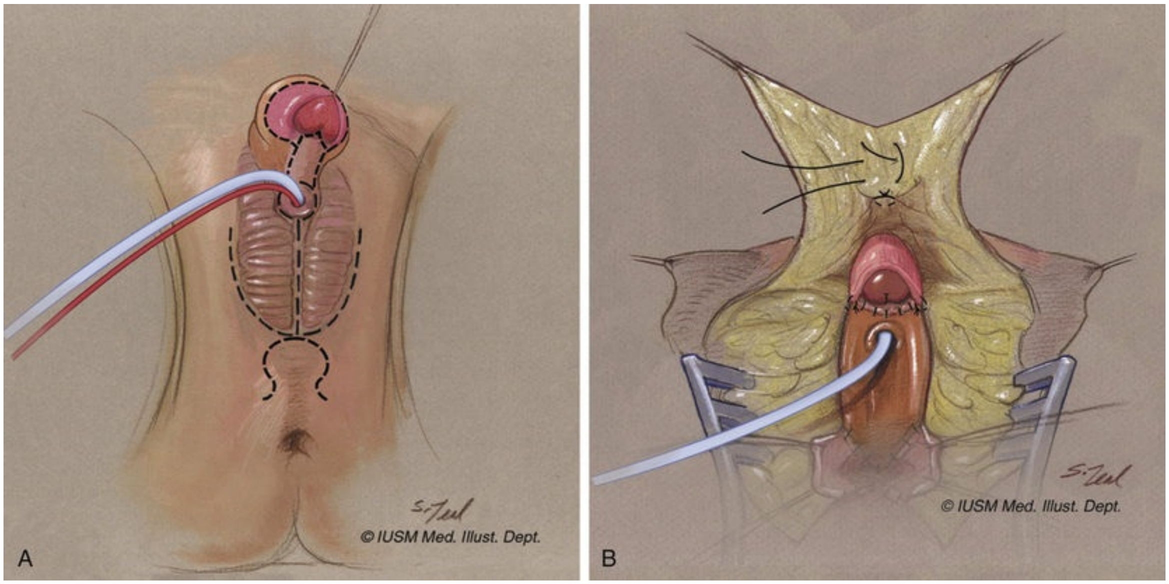

FIG. 49.13 Labioplasty. (A) Proposed incision lines for feminizing genitoplasty. Note preservation of skin cuff around glans clitoris that will be used to fashion clitoral hood. (B) After recession of the glans clitoris, the preputial skin is partially split to create the labia minora. The proximal preputial skin is plicated along its undersurface to create a "hooded" appearance to the segment of skin that will cover the glans. (© Indiana University Medical Illustration Department.)

A balanced presentation to the patient/family of all pros and cons of surgery versus no surgery is imperative, and this should be presented with the multidisciplinary team's involvement. All current data should be made available to the parents and the risks associated with each path clearly defined. The ultimate decision currently lies with the parents in concert with their multidisciplinary DSD team. These parental rights have been supported by the recent rulings of the American Medical Association's Council on Ethical and Judicial Affairs (CEJA) after 2 years of review. They rejected the idea of a moratorium on surgery. The new Endocrine Society Guidelines for CAH state that all surgical decisions remain the prerogative of families in joint decision making with experienced surgical consultants (Speiser et al., 2018). However, some advocacy groups view these parental decisions as a human rights violation for the child's rights. At the time of this writing, parental rights are currently being challenged in a number of states (California, Connecticut, Nevada, Texas), where bills have been proposed to stop any genital surgery for DSD cases if not medically necessary until the patient is of age for consent. In the following sections, the techniques described are applicable to either infants or adolescents.

Current Operative Techniques for Female Disorders of Sex Development and Urogenital Sinus Repair

Preoperatively, it is important to ensure that the patient is metabolically stable, particularly a child with CAH. Most children with CAH do not require any bowel preparation, but if there is an indication of a high confluence, complete bowel preparation with a polyethylene glycol–electrolyte solution (GoLYTELY) may be warranted. All children receive preoperative broad-spectrum antibiotics. Children with CAH must undergo “stress-dose” steroid replacement at the time of surgery. After general anesthesia, endoscopy is performed as described previously. **After passing a Fogarty catheter into the vagina, the balloon is inflated, and the catheter is clamped and left indwelling. A Foley catheter is then anchored in the bladder.** Both are kept sterile, and the child's skin is prepared with an antibiotic solution. Many surgeons prefer to place the child in lithotomy position, but I have found that this position limits vision to only the surgeon, hinders teaching, and does not allow manipulation of the child if a posterior or abdominal approach is unexpectedly needed. At the Riley Hospital for Children, all children undergo a complete lower body preparation from nipples to feet. The child's legs are wrapped, and the lower part of the body is passed through the aperture in the drapes; this facilitates access to the entire perineum and abdomen and further allows the child to be rotated either supine or prone during the procedure (Fig. 49.14). In postpubertal patients, such total body preparation may be difficult, necessitating the lithotomy position.

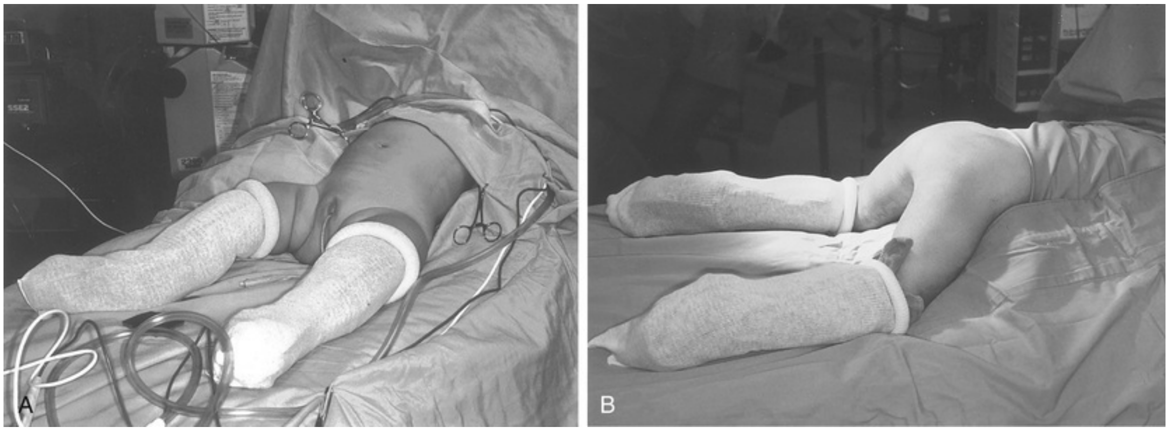

FIG. 49.14 Total lower body preparation allows both supine (A) and prone (B) approaches. (From Rink RC, Adams MC. Feminizing genitoplasty: state

of the art. *World J Urol*. 16(3):212–218, 1988.)

Key Points: Urogenital Sinus Anomalies—Reconstruction

- The three historical steps in surgical reconstruction are clitoroplasty, vaginoplasty, and labioplasty.
- As noted earlier, clitoroplasty is very controversial in infants. When performed, the glans and tunics with their neurovascular bundles must be preserved. Excision of erectile tissue, when performed, must be from the ventral aspect only.
- Vaginoplasties consist of four types: *cut-back* (generally no longer used), *flap* for a low- to mid-level confluence, *pull-through* for a high confluence, and *vaginal replacement* for a rudimentary or absent vagina. The timing of vaginoplasties is controversial.
- Labia minora are absent in urogenital sinus patients with genital ambiguity. They are reconstructed from phallic skin. The anteriorly located labia majora should be moved inferiorly.
- It is helpful to place a Fogarty catheter with the balloon inflated in the vagina. For a low confluence, an omega-shaped perineal flap provides better cosmesis. The flap is sewn into the posteriorly opened sinus, and this flap must reach to the more proximal normal-caliber vagina.
- For a high confluence, the vagina may require separation from the urinary tract at its confluence and is “pulled through” toward the perineum. The sinus opening is closed to create a urethra. With a very small, very high confluence vagina, the surgeon should strongly consider waiting until puberty for vaginoplasty.

Low Vaginal Confluence: Clitoral Hypertrophy

The vast majority of children who undergo surgery for DSD or urogenital sinus conditions have a low vaginal confluence amenable to flap vaginoplasty. They usually have clitoral hypertrophy. As noted earlier, the decision to perform clitoroplasty is very controversial in infants, but the techniques are applicable to any age. This decision should only be made after careful consideration and explanation to the patient/family of all pros, cons, risks, benefits, and controversies. Clitoroplasty and classic flap vaginoplasty are described. With the child in the supine position, a traction suture is placed through the glans, and the proposed incisions are outlined with a skin scribe. Along these lines, 0.5% lidocaine with 1 : 200,000 epinephrine is injected subcutaneously for hemostasis. The proposed incision around the glans, leaving the inner surface of the prepuce intact, is drawn along with parallel longitudinal lines on either side of the ventral mucosal strip (urethral plate equivalent) extending around the meatus. A perineal omega-shaped flap with the apex near the meatus is outlined. A Y-shaped incision line is drawn around the inferior aspect of each labia majora. The incision begins on the dorsal aspect of the clitoris, and all inner preputial skin is left intact for later construction of a clitoral hood. This skin has been shown to be second only to the glans in sensitivity (Schober and Ransley, 2002). The clitoris is degloved while keeping the ventral "urethral plate" intact with the meatus. Dissection is carried out to the level of the bifurcation of the corporeal bodies ventrally and the pubis dorsally, and care should be taken to not injure any neurovascular tissue (see Fig. 49.12). It is important to recognize that the clitoral arterial supply branches from the internal pudendal artery from Alcock's canal near the ischial tuberosity. These arteries course ventrally and are on the medial aspect of the bifurcated corpora, where they then course dorsally along the phallic shaft (Schnitzer and Donahoe, 2001). The clitoral neural bundles ascend along the ischiopubic rami and meet as paired bundles that pass along the dorsal surface and then pass largely intact into the glans (Baskin et al., 1999; O'Connell et al., 2005). My current clitoroplasty technique, regardless of patient age, is described, but, regardless of technique, the just-described clitoral innervation must not be disturbed.

A tourniquet may be placed at the base of the clitoris, or the bifurcated corpora may be compressed against the pubis with Kitner dissectors. Longitudinal incisions are then made through the Buck fascia on the ventralmost aspect of each corporeal body (Fig. 49.15); the incisions extend from the glans to the bifurcation to expose the corpora cavernosa tissue, which is dissected (often teased) from the tunics. The tunics are left undisturbed, except for the ventral incision. **No tunical tissue is excised. The dorsal neurovascular bundle should not be mobilized or disturbed in any way.** The proximal ends of the erectile tissue only are suture ligated. Other techniques involve mobilization of the neurovascular bundles from the corpora, but I believe this is more likely to injure clitoral sensitivity and vascularity. If mobilization is done, Braga and Salle

(2009) pointed out the need to dissect in the exact plane (below the second layer of the Buck fascia just beneath the tunica albuginea) to avoid neurovascular injury. Efforts to decrease the size of the glans are controversial and, if attempted, should be done with great caution. Studies by Juskiewenski et al. (1982) and Baskin et al. (1999) suggest that any glans excision should be performed ventrally near the midline (similar to hypospadias glans wings). The glans is innervated by perforating branches entering at the dorsal junction of the glans and corpora (Baskin et al., 1999). Excision of glanular epithelium to conceal the glans is to be avoided because the sensory neuropeptides are located just beneath this layer. **Remember there are no data to suggest that a large glans or clitoris is detrimental to sexual function.** The glans is now secured to the coronal stumps. In my experience, a glans sewn to the pubis results in an abnormally high prominent position (Rink and Yerkes, 2001). Pippi Salle et al. (2007) described an alternative technique whereby the corpora are dissected from the neurovascular bundle, separated, and buried beneath the labia, which allows reversibility of the clitoroplasty in those patients with later gender dysphoria.

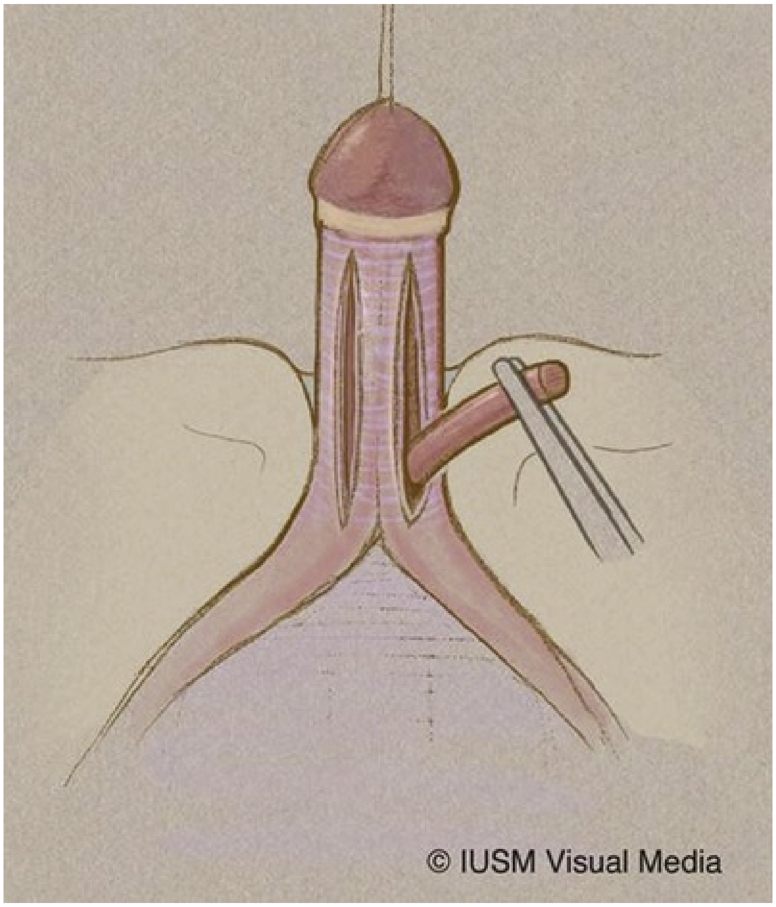

FIG. 49.15 Proposed clitoral incisions. Note the ventral location. (© Indiana University Medical Illustration Department.)

With clitoroplasty completed, the flap vaginoplasty is started. The previously outlined omega-shaped flap is incised, and the underlying fat is mobilized with the flap to expose the urogenital sinus. The flap must be made long enough to provide a tension-free anastomosis to the vagina and wide enough to provide a normal-caliber introitus without compromising the blood supply of the perineal body. It should not be redundant because this will create an obstructing mound of tissue at the introitus. The posterior wall of the sinus and vagina is now dissected free from the underlying rectum. This initial posterior step in separating the vagina from the rectum is the most difficult. With stay sutures in the meatus, the posterior wall of the sinus is opened in the midline and extended proximally into the posterior wall of the vagina. **The distal third of the vagina is usually narrowed; therefore, the posterior wall incision must be carried proximally until a normal-caliber vagina is encountered.** Sutures are placed individually through the perineal flap and then through the split posterior wall of the vagina and tied.

The mobilized phallic skin is unfurled and divided longitudinally in the midline while stopping well short of the base to allow a clitoral hood. This tissue at its base is incorporated with the preputial skin to create a clitoral hood. Labia minora are now created with this split clitoral skin, which is moved inferiorly and anastomosed to the preserved ventral plate and the lateral vaginal wall. I have found that the inferior placement of these flaps along the side of the vagina often results in an M-shaped clitoral hood, which can be overcome by plicating the dermis of the new hood to give it a more normal inverted U shape. The proposed Y-shaped incisions are now made around the inferior aspect of each labia majora. The labia are mobilized and secured inferiorly alongside the vagina as a YV-plasty. The vaginal introitus should now reside between the labia minora and majora rather than appear as an isolated hole on the perineum.

High Vaginal Confluence: With or Without Clitoral Hypertrophy

Most believe that complete separation of the vagina from the urogenital sinus with a pull-through vaginoplasty, as proposed by Hendren and Crawford (1969)**, is the best solution to a high vaginal confluence.** Braga and Salle (2009) recommend it only when the urogenital sinus is longer than 3 cm. Fortunately, this complex situation is found in only about 5% of patients with CAH (Dumanian and Donahoe, 1992). This high confluence is more commonly seen in pure urogenital sinus abnormalities. As noted earlier, I agree with Ganesan et al. (2002) that in the urogenital sinus associated with CAH, the severely virilized child may appear to have a high vaginal confluence, but it is the shared common portion of the sinus that lengthens, and there is relatively minimal shortening of the urethra. It is this lengthened common sinus in combination with the appearance of a more malelike external sphincter that gives it a high confluence appearance (Ganesan et al., 2002). Although the concept of vaginal separation and pull-through vaginoplasty was a major advance, the operation as originally described frequently resulted in an isolated vaginal opening that appeared to be separate from the remainder of the genitalia, and a mucosal lining was lacking (Passerini-Glazel, 1989). It was also technically difficult because of poor vision at the critical points (Rink et al., 1997). Several authors have addressed these issues. Passerini-Glazel (1989) used the mobilized sinus by dividing it dorsally. When tubularized with the phallic skin and folded back toward the vagina, it would create a more normal cosmetic result and provide excellent coverage in the area of the vaginal separation while helping to prevent a urethrovaginal fistula. He later used this as a flap to form the anterior vaginal wall rather than completely tubularizing it (Passerini-Glazel, 1994). Gonzalez and Fernandes (1990) used the preputial skin to construct the vaginal vestibule and anterior wall.

The critical and most technically demanding aspect of a pull-through vaginoplasty is the separation of the anterior wall of the vagina from the urethra and bladder neck. There is no obvious plane of dissection, and great care must be taken to avoid injury to the urinary tract and its sphincteric mechanism. This area is also the most difficult to visualize, and poor exposure naturally leads to poor results, with the potential for a stricture, fistula, diverticulum, or retained distal vagina (Rink and Adams, 1998). Furthermore, this is an area of significant nerve supply for the vagina and urethra. Most surgeons have positioned the patient in the supine or lithotomy position. Several authors have reported means of improving exposure for this critical area. Passerini-Glazel (1989, 1994) mobilized the vagina transtrigonally in difficult cases but later reported that this approach is seldom necessary. Similarly, the anterior sagittal transanorectal approach, or ASTRA (division of the anterior rectal wall), has provided excellent exposure for separation of the vagina and certainly should be considered for patients with a very high vaginal confluence (Di Benedetto et al., 1997; Dòmini et al., 1997; Rossi et al., 1998; Salle et al., 2012). A diverting colostomy has not been necessary with the ASTRA technique. Hendren and Atala (1995) reported lateral mobilization of the rectum but later stopped because of the difficulty of this maneuver. Rink et al. (1997) reported a midline posterior prone approach with retraction but not division of the rectum that provides excellent exposure for critical aspects of the pull-through vaginoplasty and is described here.

Endoscopy with Fogarty and Foley catheter placement and total-body preparation are as described for a flap vaginoplasty. If the child has associated clitoral hypertrophy, the clitoroplasty is performed with the child supine as described earlier for a low confluence. The child is then rotated to the prone position. In a patient with a pure urogenital sinus, the procedure is started with the patient in the prone position. Although I have found this to be very beneficial to provide improved exposure, others have not found it necessary (Ludwikowski and González, 2013).

The perineal omega-shaped flap incision is made as previously described, and then the flap is retracted posteriorly, with dissection now carried out in the midline between the posterior wall of the sinus/vagina and rectum. As dissection proceeds proximally, the rectum is easily retracted with a small Deaver retractor

(Fig. 49.16) to expose the entire urogenital sinus without the need to divide the rectum. The entire length of the sinus may be divided in the midline posteriorly to the normal caliber of the vagina. The Deaver retractor is now placed in the vagina and with upward retraction easily exposes the anterior wall of the vagina at its confluence with the sinus. This allows dissection of the vagina from the urethra under direct vision (Fig. 49.17). The tissues are quite thin in this area, and one should always err on the side of the vagina. More proximally, the dissection becomes easier. Excellent vision is also provided for tubularization of the sinus to create a urethra, which is closed in two or three layers over a Foley catheter. The anterior wall of the vagina is now mobilized inferiorly, closer to the perineum. “Pull-through” vaginoplasty is often a misnomer because frequently the separated vagina will not reach the perineum. In this situation, skin flaps have been used to reach up to the vagina (rather than the vagina “pulled through” to the perineum). Preputial skin may be sewn to the spatulated anterior vagina, as described by Gonzalez and Fernandes (1990) or as modified by Acimi (Acimi, 2013) (Fig. 49.18). When preputial skin is not available, a buttock flap or a laterally based skin flap can be used (Dumanian and Donahoe, 1992; Moriya et al., 2009; Parrott and Woodard, 1991) (Fig. 49.19). The child is returned to the supine position, and the posterior perineal flap is anastomosed to the vagina as described for the flap vaginoplasty. I believe that skin flaps are best avoided because they are more likely to stenose and may be hair bearing. The use of urogenital tissue to create the flaps is more reliable, as in the Passerini-Glazel flap.

FIG. 49.19 (A and B) A buttocks- or labial-based flap may be used to create the anterior vaginal wall in a patient with a pure urogenital sinus. (© 1999, Indiana University Medical Illustration Department.)

Labioplasty is now completed as described earlier. If a laterally based flap is required for the anterior wall, posterior relocation of the labia majora may be performed at a later stage.

In patients with a high confluence, particularly if multiple flaps have been used, the legs are bound together loosely postoperatively to prevent tension on the flaps. Although rarely required for urogenital sinus associated with CAH, the high confluence in the pure urogenital sinus patient may benefit from the ASTRA procedure noted earlier. In this procedure, with the patient prone, the posterior wall of the rectum is divided in the midline allowing excellent exposure of the high vagina for its separation and mobilization. This does not affect rectal continence and does not require a temporary colostomy.

Total and Partial Urogenital Mobilization

In 1997, Alberto Peña proposed a maneuver called ***total urogenital mobilization***

(TUM) **as a means to complete the urogenital sinus component of a cloacal repair. In this procedure, the entire sinus is dissected circumferentially and mobilized toward the perineum.** Peña noted a decrease in operative time by 70%, a superior cosmetic result, and less risk for fistula, vaginal stenosis, or acquired vaginal atresia with TUM because vaginal separation is not usually required (Peña, 1997). Since Peña's original description, TUM has been applied to several disorders, such as urogenital sinus, female exstrophy, and penile agenesis (Kropp and Cheng, 2000; Ludwikowski et al., 1999; Rink et al., 2006). Both Peña (1997) and Ludwikowski et al. (1999) reported amputation of the mobilized sinus so that the vagina and urethra can be sewn flush to the perineum. **I have reported using the mobilized sinus to provide a mucosa-lined vestibule or a Passerini flap to cover the anterior vaginal wall when a pull-through procedure is performed** (Rink and Adams, 1999; Rink et al., 2006). Jenak et al. (2001) have since reported similar use of the mobilized sinus to create a mucosal vestibule, and Hamza et al. (2001) have noted that the sinus may be used as a Passerini-like flap. There have been two recent descriptions of use of the mobilized sinus to replace the posterior perineal-based skin flap with a sinus flap. In one, the sinus is split laterally and rotated posteriorly (Rink and Cain, 2002; Rink et al., 2006). In the other, the sinus is split in half longitudinally, and the two halves are rotated inferiorly (Gosalbez et al., 2005). At the Riley Hospital for Children, I have incorporated urogenital mobilization techniques into nearly all of our urogenital sinus repairs. **This allows a midlevel confluence to reach the perineum without requiring vaginal separation. The highest-level confluences may still need a pull-through procedure with separation of the vagina and urethra,** but it is much more easily performed after the urogenital sinus has been mobilized.

TUM is often thought of as its own type of vaginoplasty but is, in fact, a technique to allow vaginoplasty that may result in the vagina being sewn flush to the perineum; however, a flap or pull-through vaginoplasty may still be required. Only rarely do I believe the vagina should be sewn flush to the perineum because of concerns of a circumferential anastomosis becoming stenotic. As described earlier, TUM is started with endoscopy to evaluate the anatomy, to note the level of the confluence, and to place a Fogarty catheter in the vagina and a Foley catheter in the bladder. A sponge is placed in the rectum, and the proposed incisions are outlined. Subcutaneous injection of 0.5% lidocaine with 1 : 200,000 epinephrine along the lines is carried out. Clitoroplasty is performed as described earlier, with the meatus of the urogenital sinus and urethral plate being circumscribed with stay sutures to allow mobilization of the sinus from the corporeal bodies. This is initially carried out to just between the bifurcation of the corporeal bodies. The clitoroplasty is now completed as described earlier. The dissection is carried out in the midline posterior to the sinus until the peritoneal reflection is reached to allow access to the entire posterior wall of the vagina (Figs. 49.20 and 49.21). This circumferential mobilization is done directly on the urogenital sinus and continues proximally beneath the pubis. As the avascular ligaments from the pubis to the sinus are divided in this area, the entire urogenital sinus is felt to "give" and move toward the perineum (Fig. 49.22).

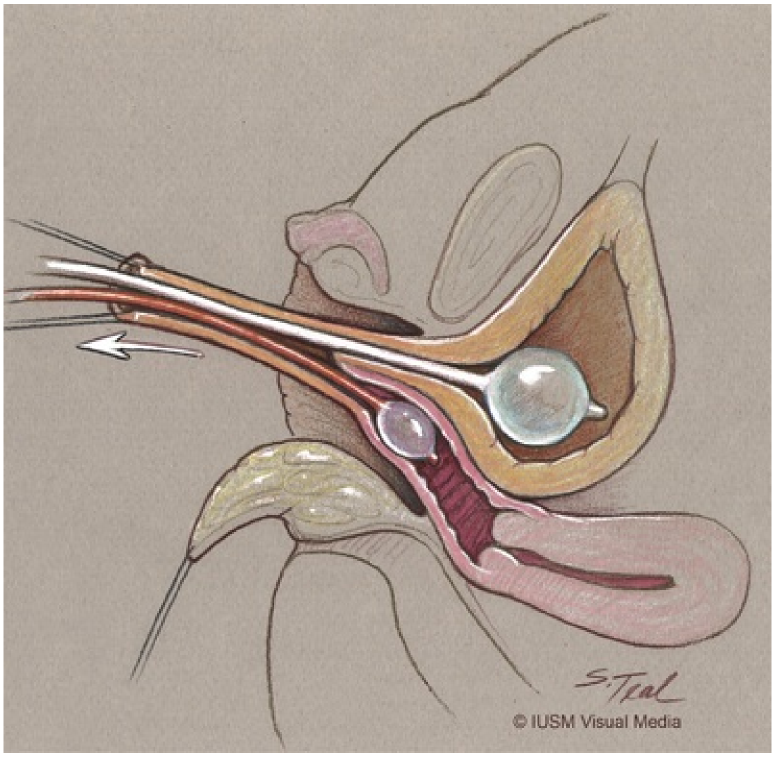

FIG. 49.22 Total urogenital mobilization. The sinus is mobilized to a position beneath the pubis. (© Indiana University Medical Illustration Department.)

The Fogarty balloon is now easily palpable in the vagina. The posterior wall of the vagina is opened between stay sutures. If the vagina is now near the perineum, it may be sewn flush to the perineum, or an omega-shaped perineal flap may be placed into the spatulated posterior wall to augment the vaginal caliber; I prefer the latter. Rather than discard the mobilized sinus, as previously reported, it is helpful to split the sinus ventrally and use it to provide a mucosa-lined vestibule (Fig. 49.23). If the vagina is still quite high, the anterior wall of the vagina should be separated from the urethra and bladder neck as in the pull-through procedure (Peña, 1997; Rink and Kaefer, 2002; Rink et al., 2006). This is most easily performed with the child in the prone position to allow direct vision. The opening in the urethra is closed in two layers. The mobilized sinus in this situation is split anteriorly and then used as a Passerini-like flap to create the anterior vagina wall (Rink and Adams, 1999; Rink et al., 2006) (Fig. 49.24). The posterior perineal flap is approximated to the spatulated posterior vaginal wall. Labioplasty is performed as previously described. TUM has achieved great popularity, and reports to date reveal excellent cosmesis and no problems with continence (Ludwikowski and González, 2013; Palmer et al., 2012). No long-term results are available.

FIG. 49.24 Total urogenital mobilization. (A1 and A2) For flap vaginoplasty, the sinus is split ventrally to create a mucosa-lined vestibule. (B1 and B2) For pull-through vaginoplasty, the sinus is split dorsally to create an anterior vaginal wall. (C) The opened sinus now becomes the anterior vaginal wall. (© Indiana University Medical Illustration Department.)

Some have expressed concern regarding the proximal circumferential dissection because of the potential risk for sphincteric musculature or nerve injury. There is concern for resultant stress incontinence or foreshortening of the vagina. **To address these concerns, Rink et al.** (2005c, 2006) **proposed *partial urogenital mobilization (PUM)*, a technique that starts with the same circumferential dissection but stops at the level of the pubourethral ligament** (Fig. 49.25). This still allows use of the mobilized sinus as described earlier to improve cosmesis, yet it avoids the aggressive retropubic and suprapubic dissection and is applicable to the majority of patients. If more mobilization is necessary for a very high vagina, TUM is easily carried out.

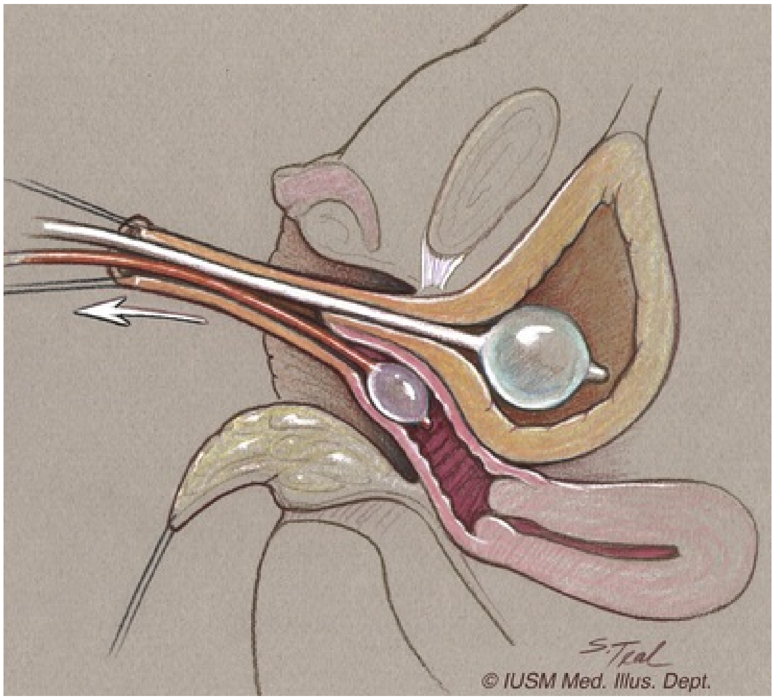

FIG. 49.25 Partial urogenital mobilization. Dissection stops at the pubourethral ligament. (© Indiana University Medical Illustration Department.)

Key Points: Urogenital Mobilization

- TUM is a technique applicable to both urogenital sinus and cloacal anomalies. The entire sinus is dissected circumferentially to above the pubis to allow the confluence to move inferiorly to the perineum.
- With the TUM or PUM technique, the mobilized sinus tissue can be used to create a mucosa-lined vestibule or an anterior or posterior vaginal wall. This sinus tissue should not be discarded.
- PUM circumferentially mobilizes the sinus to the level of the pubourethral ligament but does not extend above this level.

Results of Urogenital Sinus and Disorders of Sex Development Surgery

There are a number of significant issues when reviewing the data on surgery for DSD. The data are limited and nearly always retrospective, reviewing only small numbers of patients from a single institution, and the techniques reviewed are often outdated or not reported (Rink and Szymanski, 2015). Braga and Salle (2009) noted that available data were so poor that it was "scientifically pointless" to try to make sense of the current literature. Furthermore, most articles only look at success as an adequately open vagina with a feminized appearance. Success should include normal erotic sensation, lubrication, sexual satisfaction, orgasm, and intercourse without discomfort. These latter factors are just beginning to be studied. The psychological aspects of both early surgery without the child's consent versus raising a child with genital atypia remain largely unexplored. **Cosmetic and early functional results have uniformly been reported to be favorable. Long-term outcomes are of more concern.** Unfortunately, in these studies it is often difficult to tell what procedures were done for what degree of severity of urogenital sinus, and none of the studies include data on the quality of endocrinologic control in these patients. Looking at what data are available, Jones et al. (1976) noted that 25 of 84 patients undergoing vaginoplasty required a secondary procedure to provide a vaginal outlet satisfactory for intercourse; 5 of these 25 also required a third procedure. **The poor results were caused by failure to exteriorize the vagina initially or by scar formation. The distal vagina is always narrow. The normal-caliber**

vagina must always be reached and exteriorized with current procedures. Sotiropoulos et al. (1976) found that all patients undergoing prepubertal vaginoplasty required revision at puberty. Azziz et al. (1986) reported the results of attempted coitus in 42 women with CAH 23.6 years after vagina repair. Satisfactory coitus was noted in 62% (46% in salt wasters and 87% in those with the non–salt-losing form). There was a less favorable outcome when the initial procedure was performed before 1 year of age. Thirty secondary or tertiary procedures were needed to achieve the final results. These data are widely quoted, but almost all of these patients initially underwent a cut-back vaginoplasty ("incision of the urogenital sinus"), which is a procedure only rarely used because it does not adequately open the vagina to the proximal normal caliber; specifically, the distal end of the vagina is narrowed and thus will be stenotic. Revisions for these patients involved the performance of a flap vaginoplasty, which currently would probably have been the initial procedure. In a series from Johns Hopkins Hospital, 28 patients (32% lost to follow-up) had adequate follow-up, 22 (78.6%) of whom needed further vaginal surgery (Bailez et al., 1992). Bailez et al. (1992) noted that if secondary surgery was needed for vaginal stenosis, success rates were high when the procedure was performed near puberty, with only 8 of 18 needing a secondary procedure requiring a flap. This group also reported less favorable results in those younger than 1 year of age (Bailez et al, 1992). Nihoul-Fekete et al. (1982) noted that 30% of 43 CAH patients required secondary surgery. Hendren and Atala (1995) reported on 16 patients with high vaginal confluence and noted that 6 of 9 adults had satisfactory coitus and 2 had vaginal stenosis.

Fourteen girls with CAH, 11 to 15 years of age, who had undergone genitoplasty at a mean age of 2.5 years were assessed under anesthesia by Alizai et al. (1999), who noted that 13 of the 14 required additional vaginal surgery. Stenosis was seen in 43%, and persistent urogenital sinus with or without fibrosis in 50%. Minto et al. (2003) found that 39% of 28 patients required secondary surgery, and 11% required a third procedure. Al-Bassam and Gado (2004) noted vaginal stenosis in 16% of their patients who underwent various types of vaginoplasties (43 vaginoplasties: 26 flap, 11 pull-through, 2 cut-back, 3 sigmoid vaginal replacement, 1 abdomino-perineal pull-through). Nearly all underwent vaginal dilation. Nordenskjöld et al. (2008) noted vaginal stenosis in 37% of their operated CAH patients, with 15 of 50 noting painful intercourse. However 24 of the 41 vaginoplasties were cut-backs, with 10 flaps and 7 combinations. In a cross-sectional study of Dutch women older than 15 years of age, 7 of 13 single-stage repairs required secondary surgery, and of 20 women who had intercourse, 8 complained of dyspareunia, but only 2 had vaginal stenosis (van der Zwan et al., 2013). It is tempting to assume that postpubertal vaginal surgery may result in more favorable outcomes, but there are no data to support this assumption. Furthermore, Eroglu et al. (2004) actually noted less vaginal stenosis in those patients who underwent early single-stage repair (3.4%) than in those who underwent late vaginoplasty (42.8%). Lean et al. (2007) noted no difference whether the surgery was done before or after 2 years of age. In their series of 32 patients, they noted good cosmesis in 72%, satisfactory in 22%, and poor in 6%. They believed that the planned one-stage operation gave better results than the planned multistage procedure, with only 2 of the 32 former patients requiring further major surgery and 3 needing minor revisions. Al-Bassam and Gado (2004) also recommended a single-stage repair at 3 to 6 months of age. It may be that the level of vaginal confluence and number of procedures is far more predictive of outcome than is the timing (van der Zwan et al., 2013).

It seems clear that a single-stage early vaginoplasty will often require a secondary repair after puberty, but this should be expected because the orifice is likely to remain the size that was created given that there is no flow through the orifice in childhood. In my experience, the secondary refinements are easily performed.

Surgical techniques to reduce clitoral size have dramatically improved and are now based on our current knowledge of clitoral neuroanatomy. Even though no long-term results are available for current techniques, some long-term results are now being reported for relatively modern techniques. Alizai et al. (1999) found clitoroplasty results to be unsatisfactory in 46% of the patients they assessed. **Gearhart et al.** (1995) **looked at pudendal evoked potentials after clitoroplasty and noted that modern clitoroplasties preserve nerve conduction in the dorsal neurovascular bundle.** Barrett and Gonzales (1980) found intact sensation in all of their patients after clitoroplasty. Chase (1996) reported that even with normal evoked potentials there may be an absence of sensation and orgasm. I have not noted vascularization defects after modern clitoroplasty. It is clear that further long-term studies are necessary. Minto et al. (2003) found the clitoris to be cosmetically normal in 59% of patients who had undergone clitoral surgery, but it was excessive in 20%, large in 7%, small in 7%, and absent in 7%. This group also reported that hot, cold, and vibratory sensation was markedly altered as recorded by a genitosensory analyzer.

Sensation alone may be a poor indication of clitoral normality after surgery. Further studies to analyze the newest techniques are warranted. The erotic sensitivity and potential for orgasm should be studied. More recently, Nordenskjöld et al. (2008) compared 62 CAH patients with 62 controls. Of the 49 who underwent clitoroplasty, 16 had 1 operation, 14 had 2, 4 had 3, 4 had 4, and 11 had between 5 and 10 operative procedures. Twenty percent were not satisfied with their surgery; they thought there was decreased sensitivity. However, 50% of the nonoperated patients thought their clitoris was too large. There was no difference in the ability to achieve orgasm between the two groups. The authors noted that women with CAH were less satisfied with their genitalia whether operated or not. Nordenström et al. (2010) noted that clitoral sensitivity was affected in nearly all patients who had undergone clitoroplasty. However, those with partial clitoral resection sparing more nerve function had a more favorable outcome and did not differ from those with no surgery. Initial degree of virilization also affected clitoral sensitivity.

The results of TUM and PUM are very early. These procedures are technically easier, and the cosmetic results are superior, but whether the functional results are better is unknown. The potential for stress incontinence or denervation of the sphincteric mechanisms also is unknown. Most authors to date have not found continence to be altered by TUM (Hamza et al., 2001; Jesus et al., 2018; Kryger and Gonzales, 2004; Ludwikowski and González, 2013; Palmer et al., 2012; Rink and Adams, 1999; Rink et al., 2007). Until these results are available, these procedures should be used with caution.

Recently there has been an effort to understand sexual function and mental health after feminizing genitoplasty. Fagerholm et al. (2012) noted that quality of life and health-related quality of life studies appeared normal in most patients and that mental health was similar to or better than published data from Finland. There were 5 of 24 patients who had some poorer scores because of distressful memories of too-late surgery, the operative treatment itself, or poor sexual function. This same group also noted that intercoital relationships started later in females who underwent genital reconstruction in childhood as compared with the normal population. In addition, the patients preferred surgery to be done early in life. In a study of 62 Swedish women with CAH, Nordenström et al. (2010) reported several interesting results. Overall satisfaction with sexual function after feminizing genitoplasty was as good as controls except for patients with salt-wasting CAH, the most severely affected. The cosmetic score did not differ between those who were satisfied and those who were not, and cosmetic outcome did not contribute to sexual orientation. In this study, as in the study by Wisniewski et al. (2004), the physicians perceived the genital appearance as better than did the patients. Callens et al. (2012) noted that feminizing surgery did not seem to improve or hamper psychosexual outcome, especially in those patients with severe virilization. In a recent review of the literature, the prevalence of homosexuality and bisexuality was noted to be increased in CAH patients versus the non-CAH group and was found to be greater in salt-wasting versus non–salt-wasting patients (Gondim et al., 2018).

There has been some concern that lower urinary tract symptoms are more likely in those patients with CAH (Davies et al., 2005), but in the study by Fagerholm et al. (2013), symptoms did not seem to differ in female DSD patients versus controls. Occasional lower urinary tract symptoms were common in both patients and controls.

Timing of vaginoplasty remains quite controversial. Although the few reported long-term studies suggest that delayed vaginoplasty may be preferable, most children currently continue to undergo vaginoplasty as infants, particularly for the CAH group (Rink and Whittam, 2014; Yankovic et al., 2013). Most would recommend delaying vaginoplasty for the patient with a small (<3 cm), very high confluence vagina. They argue that the available long-term studies are based on outdated techniques and that there are tremendous surgical advantages to a single-stage repair. If early vaginoplasty is performed, it is well recognized that secondary introitoplasty may be necessary, but this is usually accomplished easily. The argument, which will not be settled soon, contrasts two approaches, both of which usually result in two procedures: (1) a simple procedure in an infant (i.e., clitorolabioplasty) with a postpubertal extensive procedure (i.e., vaginoplasty) or (2) an extensive single-stage clitorolabiovaginoplasty in an infant with a simple introitoplasty in the postpubertal period. Should a moratorium be mandated, this would never be answered. There is also controversy on the correct timing to share information with the affected child. Unfortunately, research on when to convey information is virtually nonexistent (Sandberg et al., 2012). In an effort to support guideline development for CAH by the Pediatric Endocrine Society, a meta-analysis was performed of all available outcomes data in the literature from throughout the world. (Elmasri et al., 2018). There were 29 observational (1178 patients) studies that met inclusion criteria. The mean age at surgery was 2.7 years, and average follow-up was 10.3 years. The data points were not represented in all studies, but their conclusions were that 88.7% had female gender identity. The Female Sexual Index Score was

25.3 (36 maximum), suggesting some residual difficulties. The authors noted one study reported significantly lower scores than controls, and three others noted no significant difference from controls. Most patients were sexually active and satisfied with the surgical outcomes, but only 1 in 2 reported comfortable intercourse. Vaginal stenosis was found in 27%, but fistulas, urinary incontinence, and urinary tract infections were much less common. Although these data are helpful in discussions with CAH patients and their families, they have multiple limitations and do not compare early versus later surgery.

Several studies have noted that the most important factor affecting results is whether there was a surgeon or surgical team with a special interest in feminizing genitoplasty procedures (Creighton et al., 2001; Lean et al., 2007; Nordenskjöld et al., 2008). This suggests that support for Centers of Excellence may be appropriate for the care of children with DSD. Comprehensive CAH Centers have been designated in the United States by the CARES Foundation.

Key Points: Urogenital Sinus Anomalies—Outcomes of Reconstruction

- It is clear that neonatal vaginoplasties will usually require a secondary procedure for stenosis after puberty (25% to 100%).
- Successful coitus is often reported, but further studies should note sexual satisfaction, lubrication, erotic sensitivity, and nonpainful coitus.
- Current techniques of clitoroplasty seem unlikely to injure sensation, but newer studies question whether sensitivity is an adequate indication of clitoral function. Some studies note decreased sensation with newer techniques.

Surgical Reconstruction for Cloacal Malformations

Initial Management, Timing, and Principles

The initial management of cloacal anomaly involves stabilization because the child is often quite ill with abdominal distention that at times results in respiratory compromise. As with all other anomalies, its management has evolved. Historically, after decompression of the distended organs, it was common practice to perform a rectal pull-through procedure; genitourinary reconstruction followed at a later date, if at all (Okonkwo and Crocker, 1977). Hall et al. (1985) suggested that the vaginal surgery be done after puberty, when estrogen levels are higher. Although it is tempting to perform a pull-through procedure only, it is now thought by the majority of authors that piecemeal repair of the cloaca is a disservice to the child and is absolutely contraindicated. It is optimal to repair all abnormalities (i.e., rectal, vaginal, and urethral) in a single stage (Kay and Tank, 1977; Mollitt et al., 1981). This allows the best exposure for the difficult rectal and vaginal separation. Furthermore, the tissues have not been previously violated, and the rectum does not require remobilization. Hendren (1982, 1986) pointed out that rectal pull-through should never be done as a separate procedure. Of his 154 patients with cloacal anomaly, 60 were secondary cases, many of whom had undergone a previous pull-through procedure. Definitive repair in this situation often requires repeat rectal mobilization. Raffensperger (1988) proposed neonatal complete repair but later noted that this may not be appropriate. Levitt and Peña (2005) have stated that there are three pitfalls in the management of neonates with cloacae: (1) failure to recognize and manage hydrocolpos, (2) colostomy or vesicostomy problems, and (3) clinical misdiagnosis. Recently, Kittur and Vora (2017) and Bal et al. (2017) have offered a different approach. They recommend avoiding urethrovaginal reconstruction in infancy and performing only the anorectal surgery. They opt for a Mitfanoff procedure in those requiring clean intermittent catheterization (CIC). Peripubertal vaginal reconstruction did not worsen voiding dynamics or continence and overall decreased the number of children requiring CIC. They believe that this approach lessens the significant complications of early urethrovaginal surgery they had seen. They believe that these complications, which may put the urinary and genital tract at risk and result in worsening renal function, are best avoided.

Surgical management now involves four basic steps: (1) decompression of the gastrointestinal tract, (2) decompression of the genitourinary tract, (3) correction of nephron-destructive or potentially lethal urinary anomalies, and (4) definitive repair of the cloaca.

Decompression of the Gastrointestinal Tract

Decompression of the gastrointestinal tract is done by colostomy. Although nearly all surgeons agree on the need for colostomy initially, the best anatomic location of the colostomy is debated. Hendren initially recommended a low-loop colostomy but more recently has performed a right transverse colon divided colostomy (Hendren, 1982, 1986, 1998). This change was prompted by difficulty in obtaining a bowel segment for vaginoplasty during the rectal pull-through procedure when a low colostomy has been performed. A divided transverse colostomy keeps the left colic blood supply intact (Hendren, 1992). Peña, as cited by Spitz and Coran (2006), preferred a descending colostomy because there was less surface area for resorption of urine. A divided colostomy in the descending colon just after the colon takes off from its retroperitoneal attachment is now recommended by Levitt and Peña (2005). This procedure maintains the availability of enough distal colon for future pull-through, and prolapse is less likely to occur. However, Peña did recommend leaving a long segment of sigmoid to prevent a difficult pull-through requiring abdominal exploration. Levitt and Peña (2005) noted that 24 of 361 patients had a colostomy too low that interfered with the rectal pull-through. I have favored a proximal colostomy but have at times found clinically challenging acidosis caused by urine absorption through the colonic mucosa. Masuko et al. (2005) reported successful decompression of the colon by balloon catheter drainage with irrigation of the bowel three times per day. This avoided temporary colostomy and allowed a single-stage repair. Malrotation in patients with ARM has the same frequency as in the general population but is more common in severe malformations. These should be recognized and addressed at the time of colostomy, and the appendix should be preserved for potential appendicocecostomy later.

At the time of colostomy, endoscopy may be performed to more clearly define the anatomy and to aid in decompression of the urinary tract. In my experience, as the cystoscope advances proximally through the cloacal channel, it tends to enter the vagina (or vaginas). In fact, entrance into the urethra/bladder can be extremely difficult in a neonate with a distended vagina because the vagina compresses the bladder to the anterior abdominal wall and obstructs the bladder neck. Drainage plus irrigation of the vagina (or vaginas) not only allows decompression and relief of abdominal distention but also may allow visualization of the bladder. Often, the rectal fistula is also difficult to locate; as noted earlier, it is more often found within the septum of the duplicated vaginas but can enter at almost any location. With a combination of irrigation through the fistula and through the distal limb of the colostomy, the inspissated mucus and meconium can easily be cleared. It is often helpful to leave small feeding tubes in all channels and then obtain radiographic studies to further delineate the anatomy. In my experience, this is best done in the radiology suite with fluoroscopy.

Decompression of the Genitourinary Tract

Even after decompression of all structures draining into the cloaca, at times voiding continues into the vagina (or vaginas) or the rectum (or both) and results in rapid distention of these structures with subsequent poor urinary drainage, persistent hydronephrosis, abdominal distention, urinary infection, and hyperchloremic acidosis. This can generally be managed by intermittent catheterization. The catheter often enters the vagina rather than the bladder, but it still functions to drain and decompress the genitourinary tract (Hendren, 1992). If the desired decompression is not achieved, further maneuvers are required. I agree with Hendren that, in a long urethra-like cloaca, catheterization can at times be difficult, and a cut-back procedure (opening the cloaca) may be helpful to aid catheterization (Fig. 49.26). If this approach fails, further decompression can be achieved by either vesicostomy or vaginostomy (Kay and Tank, 1977). Levitt and Peña (2005, 2010) have found vaginostomy or tube vaginostomy to be helpful, but it is my belief that CIC should be the first-line treatment because it will usually keep the vagina adequately decompressed. Only when CIC fails should vesicostomy or vaginostomy be performed. The concern of tethering the vagina to the abdominal wall with later difficulty doing a pull-through or TUM has led some to recommend vesicostomy over vaginostomy, but others have found this not to be a concern. It also necessitates an abdominal procedure. Levitt and Peña (2005) found that 25% of their cloaca patients had hydrocolpos but that in 59% of them it was either not identified or mismanaged. This resulted in significant morbidity from ureteral obstruction, urinary tract infection, acidosis, and failure to thrive. Adequate vaginal drainage resulted in resolution of these problems. Chalmers et al. (2015) recently reported that initial management with CIC was equivalent to diversion by vesicostomy or vaginostomy in protecting the urinary tract and preventing hydrocolpos.

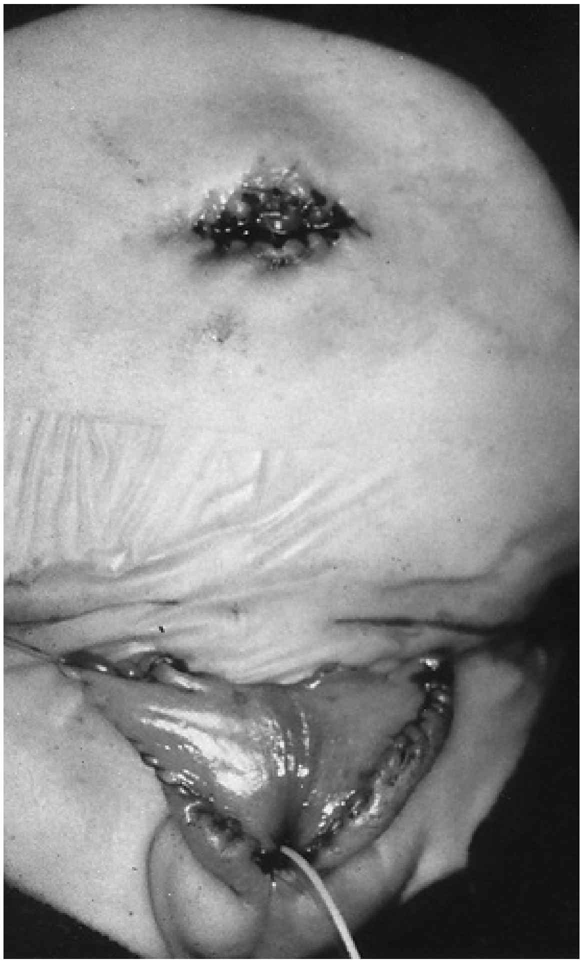

FIG. 49.26 The urethra-like cloaca is opened with a catheter in place; vesicostomy has also been performed.

Repair of Obstructive Urinary and Other Pathology

The third stage of care of a child with a cloacal anomaly is repair of any obstructive urinary tract pathologic process. Renal structural abnormalities, some of which were obstructive, have been identified in 60% to 83% of patients with persistent cloaca (Rink et al., 2005b; Warne et al., 2003). In those patients with a common channel longer than 3 cm, 91% had urologic defects (Peña et al., 2004). At times, these anomalies are ignored early on while awaiting definitive cloacal repair, but this practice should be avoided. Obstructive lesions should be treated promptly. However, vesicoureteral reflux, which is quite common, can generally be managed medically if urinary infection is prevented. Other organ system anomalies (e.g., cardiac, spinal cord) should be fully evaluated. Some may require repair during this phase.

Definitive Repair of Cloacal Malformations

Definitive repair of a cloaca is usually carried out at 6 to 12 months of age, but obviously the child must be well nourished and thriving to proceed with repair. In healthy thriving children, Peña et al. (2004) operate at 1 month of age. Definitive repair should never occur until the urinary tract has been evaluated and hydrocolpos has been ruled out. If endoscopy has not been performed previously, it may be helpful as a separate procedure before the definitive repair. Defining the anatomy can be tedious, and it is helpful to thoroughly cleanse the distal colonic segment, which usually requires irrigation from the mucous fistula, and the distal limb of the colostomy. A standard GoLYTELY bowel preparation should also be done.

Operative Technique: Cloaca

The definitive repair begins with endoscopy to reacquaint the surgeon with the anatomy. I have also found it is helpful to place a Foley catheter in the bladder and different-colored Fogarty catheters in the vagina (or vaginas) and rectum. The catheters are kept sterile during preparation. As described earlier for urogenital sinus repair, a complete lower body preparation with an antibacterial solution is done circumferentially from the level of the nipples to the toes, and the legs are wrapped sterilely. Such preparation allows prone and supine positioning for perineal and abdominal surgery.

The definitive posterior sagittal anorectovaginourethroplasty (PSARVUP) is begun with the child in the prone position and the pelvis elevated on rolls to achieve a jackknife position. An electrical stimulator is used to determine the area of maximal contraction, which is marked with a skin scribe and with stay sutures for later rectal placement. The proposed locations of the perineal body and vagina are also marked (Fig. 49.27). I agree with Hendren (1992) that it is at times helpful to have a sound in the common cloacal channel, but the Foley and Fogarty catheters usually suffice. The entire dissection is done in the midline until mobilization of the rectum and vagina is begun. The most important advances of Peña's PSARVUP procedure are that it allows identification of the external sphincter and muscle complex of the rectum and provides excellent exposure for separation of the rectum and vagina (or vaginas) from the cloaca.

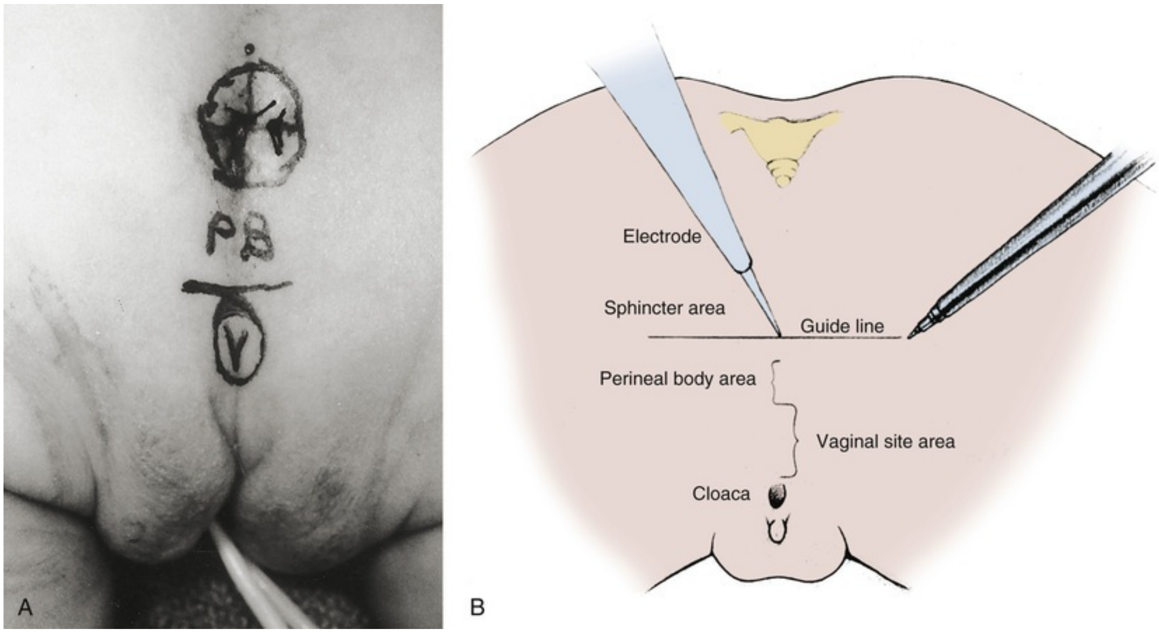

FIG. 49.27 (A) Cloaca: proposed location of the vagina (V) and perineal body (PB). (B) Rectal location is identified by electrical stimulation.

The initial incision extends from the tip of the coccyx in the midline to the posterior aspect of the cloacal orifice. Sutures mark the sphincteric muscular structures on either side as they are encountered. I have found it helpful to open the common cloaca in the midline posteriorly to the level of the confluences to allow easy identification of the rectal and vaginal insertions. With TUM, this is less appropriate because it may limit the options for use of the sinus in the reconstruction as described earlier for a urogenital sinus. When the rectal fistula is identified, it is opened posteriorly and multiple silk stay sutures are placed. These sutures are helpful in mobilizing the rectum away from the vagina (or vaginas). It is important to remember that the structures share a common wall initially, and it is better to enter the vagina than either the rectum or urethra. Circumferential dissection of the rectum to well above the sacrum may be necessary. Separation of the peritoneum can be done from this position. Rarely, a child with a very high rectal confluence needs to be turned to the supine position for abdominal exploration to free the rectum more proximally. Levitt and Peña (2010) have noted abdominal surgery to be more likely when the common channel is greater than 3 cm in length. Once adequate rectal mobilization to allow a tension-free anastomosis to the perineal skin has been achieved, the rectal stay sutures are used to retract the rectum from the genitourinary structures.

In the classic PSARVUP procedure, the vagina is now separated from the sinus. This dissection is even more tedious and difficult than the rectal separation. With TUM (described later), which has now achieved widespread acceptance for cloacal repair, the vagina may not require separation. In classic vaginal separation, as noted earlier, it is an error to enter the urinary tract during vaginal mobilization. Side-by-side vaginal duplication is most common, and the midline septum has been incised with electrocautery during the initial endoscopy. Hendren (1998) noted that 66 patients had a single vagina, 68 had two, and 20 had none. Pradhan et al. (2018) noted vaginal and uterine duplication in 63%. The Fogarty catheter (or catheters) within the vagina is easily palpable, and the posterior aspect of the vagina is opened at the level of the confluence. Again, circumferential stay sutures are very helpful in separating the vagina from the urethra and bladder. A malleable retractor inserted into the opened posterior vaginal wall exposes the anterior wall confluence for separation. Sharp dissection is less likely to injure the urinary tract than is cautery. Making dissection even more difficult is the realization that frequently the vagina almost encircles the urethra. Failure to recognize this situation can result in injury to these structures. Use of the stay suture for traction aids in further mobilization of the vagina (or vaginas). The outer wall of the vagina appears white, and identification of this color is helpful. Great care should be taken to avoid devascularization of the vagina during mobilization. Usually, vaginal mobilization allows the vagina to be “pulled through” to a position near the perineum. If after significant mobilization it still does not reach the perineum, skin flaps can be used to reach the spatulated vagina. With an extremely high vagina or the rare vaginal agenesis, it may be necessary to interpose a bowel segment to reach the perineum, which obviously requires abdominal surgery. With a very dilated vagina, a vaginal flap or vaginal “switch” can be created to reach the perineum, although care must be taken to avoid devascularization and stenosis (Hendren, 1986; Peña, 1989; Peña et al., 2004).

Before the vagina is brought to the perineum, the openings in the common cloacal channel should be closed in two to three layers with absorbable suture to create a urethra. If the cloaca is large and resembles a vagina, it needs to be opened in its entirety and tailored over the Foley catheter. The vagina is then secured to the perineum. If there is any concern about vaginal injury, the vagina should be rotated to avoid overlapping suture lines (Hendren, 1992). The Foley catheter is left indwelling for 2 weeks.

Some surgeons have more recently noted that laparoscopic-assisted PSARVUP can help in achieving a low dissection of the fistula and accurate placements of the rectal pull-through, while allowing excellent visualization of the pelvic structures (Tei et al., 2003). Single- incision laparoscopic procedures have been performed, and Ren et al. have noted single incision laparoscopic assisted anorectoplasty to be as effective as three port assisted procedures with improved cosmesis (Ren et al., 2018; Wang et al., 2016).

The perineal body is now reconstructed, and the rectum is pulled through to the perineum. Peña (1989) stressed the importance of tailoring the widened rectum. The amount of tailoring differs in each patient. The muscles must meet posterior to the rectum. The rectum is placed in the center of the sphincteric muscle mass and anastomosed to the skin. Rectal dilation is begun gradually at 2 to 3 weeks after surgery, and the colostomy is closed in 3 months if all has healed well.

Once the urethral catheter has been removed, it is imperative to monitor the urinary tract and voiding dynamics closely because poor emptying secondary to a neuropathic component is seen in almost one-third of patients. If any concern arises about the child's ability to empty, CIC should be started and continued until normal bladder dynamics are ensured. Failure to do so can ultimately result in urinary tract infection, hydronephrosis, and even loss of renal function.

Peña's TUM technique is now widely accepted for cloacal anomalies. It is a technically easier procedure that requires less time with less blood loss. The basic technique involves 360-degree mobilization of the entire urogenital sinus after the rectum has been separated. The technique at this point is not different from that described earlier for TUM for urogenital sinus abnormalities. I have found this technique to be extremely helpful. It makes the most difficult part of cloacal surgery, vaginal separation, much more easily performed when necessary. If the confluence is only 2 to 3 cm from the perineum, separation may not be even necessary. In patients with a high vaginal confluence, separation may still be necessary, but it is much more easily accomplished (Rink et al., 1997). Concerns regarding continence have been raised, but to date the results have not been different from those with standard repairs. Long-term results of the TUM procedure are needed. Our group has noted that the most important factor in urogenital sinus reconstruction is the distance of the bladder neck to vaginal confluence (true urethral length). Using this concept, the group at Nationwide Children's Hospital has recently reported this importance in cloacal anomalies and has used this urethral length to promote a new algorithm for cloacal repair (Wood et al., 2017). In their new approach, they note that if the urethra is less than 1.5 cm, doing a TUM may result in urinary leakage and should be avoided. In those with a short urethra, one should separate the vagina from the urethra/urogenital sinus, and the urethra is reconstructed or the common sinus used as a urethra. This group later reviewed urethral length in normal healthy females by VCUG and found the normal mean female urethral length to be 2.43 cm (2.50 cm for 6 to 12 months of age, 2.31 for 12 to 24 months of age, and 2.59 for 24 to 36 months of age) and that having a urethral length greater than 1.5 cm should keep the bladder neck above the urogenital diaphragm (Halleran et al., 2019).

Key Points: Cloacal Reconstruction

- Cloacal reconstruction involves four steps: (1) decompression of the gastrointestinal tract (colostomy); (2) decompression of the urinary tract (CIC, vesicostomy, vaginostomy); (3) correction of associated organ systems anomalies; and (4) cloacal repair (PSARVUP).
- TUM is now commonly used for cloacal anomalies after the rectum is separated.
- The results of cloacal repairs are often based on the presence or absence of a normal spinal cord. CIC is frequently required, as is a bowel program, to achieve urinary and fecal continence.

Results of Cloacal Surgery

Cloacal anomalies are exceedingly challenging to repair. The anatomy is complex and differs from patient to patient. The surgeon must be prepared for a long, tedious procedure, must be imaginative, and must be willing to handle the tissues with great care. One might assume from this preface that the results would be dismal. On the contrary, most patients lead a productive life. We surgeons are indebted to Drs. W. Hardy Hendren and Alberto Peña for their pioneering work on children with cloacal anomalies, and their willingness to document their results.

Results have generally been reviewed in terms of urinary continence, fecal continence, and sexual capability; in the future, results should also focus on erotic sensitivity and fertility, pain-free intercourse, and orgasm and quality of life. Early results from a urinary standpoint were dismal: Chappell and Bleloch (1973) reported that all 5 of their patients had some degree of incontinence postoperatively, and Bartholomew and Gonzales (1978) had 5 of 7 patients wet after reconstruction. **It is now clear that a high percentage of patients have a neuropathic component to their incontinence.** In a recent series reported from the Cincinnati Children's Hospital, 89% of those with a common channel greater than 3.5 cm had a neuropathic bladder, whereas only 48% of those with a common channel less than 3.5 cm did (DeFoor et al., 2015). De Filippo et al. (1999) reported urodynamic data on 26 patients with ARMs (including 6 with cloacal anomalies). In this study, 21 of the 26 had preoperative leak point pressures greater than 40 cm H_2O, and 15 had a normal MRI of the spine. This means that even those not demonstrating a neurologic abnormality may have abnormally high outlet resistance, which adds to the risk for incontinence and upper tract changes. Muller et al. (2014) showed that the type of spinal abnormality may affect continence rates, with the short spinal cord having the greatest impact. Of Hendren's 141 patients, 83 (59%) voided spontaneously with control, 40 (28%) required CIC, 4 (3%) had undergone urinary diversion, and 1 (0.7%) was continent with urinary diversion; only 5 (3.5%) were wet, and in 8 the results were too early to assess (Hendren, 1998). Peña et al. (2004) reported a review of 339 patients operated on for cloacal anomalies, 193 of whom were evaluated for urinary continence. They found that spontaneous voiding was related to length of the common channel. Overall continence with spontaneous voiding occurred in 54%. Another 46% were dry with CIC (24% with a native urethra, 22% with a Mitrofanoff channel). However, when the common channel was less than 3 cm, 28% required CIC; if greater than 3 cm, 78% required CIC. Warne et al. (2002b) achieved 80% “social continence,” but only 22% spontaneously voided, 12% performed CIC alone, and 46% required reconstructive urologic surgery to achieve continence (mean number of operations, 4.7). They likewise found that patients with a common channel longer than 3 cm were less likely to void spontaneously (12% vs. 31%). In the series by Rink et al. (2005b), 86% were dry, but only one-third were continent with spontaneous voiding. The remainder required CIC with or without lower urinary reconstruction (Table 49.1). After TUM, spontaneous voiding occurred in 43% to 66% of patients (Levitt and Peña, 2010). Warne et al. (2002b) also noted that a good bladder neck, short common channel, normal sacrum, and two normal kidneys were all good prognostic signs for continence and spontaneous voiding. I am in agreement with Peña and Levitt (2003) that voiding abnormalities are generally related to a noncontractile bladder and warrant CIC, but Warne et al. (2002b) found hyperreflexia to be the predominant pattern in those with abnormal dynamics. It is important to note that 75% of their patients had an abnormal sacrum. In a systematic review of the largest pooled cohort of patients, less than one-half voided spontaneously (22% to 54%); 42% of patients required CIC, and 22% had urinary diversion (Versteegh et al., 2013). Long-term renal function has been a major concern in those with persistent cloaca. At presentation, renal functional impairment must be identified and treated. In 44 patients reported, 19 had hydronephrosis, 19 had vesicoureteral reflux, and chronic kidney disease (CKD) was noted to be stage I to II in 30, stage III in 5, and stage IV in 1. However, DeFoor et al. (2015) showed in these patients that with aggressive diagnosis of underlying anatomic and functional urinary tract dysfunction combined with aggressive modern bladder management (i.e., CIC, diversion, augmentation), renal function can been preserved even in those with CKD.

TABLE 49.1

Continence Rates After Cloacal Surgery

REFERENCE	VOIDING SPONTANEOUSLY	DRY WITH CIC ± CONTINENT RECTUM
Hendren, 1998	0.62	0.34
Peña et al., 2004	0.54	0.46
Warne et al., 2002b	0.22	0.58
Rink et al., 2005b	0.33	0.53

CIC, Clean intermittent catheterization.

Fecal continence is directly related to neurologic status (Peña, 1989)**. Hendren** (1992) **noted that certain factors bode well for continence: good perineal raphe, well-defined anal dimple, normal spine, normal MRI, and brisk muscle reflex** (Hendren, 1992). In 105 patients, Hendren (1992) noted that 47 had normal bowel function, 27 required enemas, 7 had a colostomy, 7 had fecal soiling, and 4 with an anterior anus had normal control. Peña et al. (2004) reported that 60% of 156 patients had voluntary bowel movements, but only 28% of them never soiled. The 40% who are fecally incontinent remain "clean" with a bowel management program. The Malone antegrade continence enema (MACE) appendicovesicostomy has been very helpful in preventing constipation and achieving fecal continence in those refractory to bowel management programs. Rintala's report on long-term fecal outcomes noted voluntary bowel movements in 57%, but 33% had total fecal incontinence with many to most needing a bowel management program (Rintala, 2016). Approximately 17% had opted for fecal diversion. Fecal continence rates were thought to improve in adolescents/adults over children, and less constipation was noted in the older group. In summary, more than one-half of these patients will have major defects in urinary and anorectal function long term.

Vaginal and perineal reconstruction in cloacal anomalies has been associated with a number of complications including introital stenosis, retained vaginal septum, persistent rectovestibular fistula, persistent urogenital sinus, and inadequate perineal body (Vilanova-Sanchez et al., 2018). An inadequate perineal body was generally related to an anterior placed rectum at the time of the initial PSARVU. Fifteen of 28 patients referred to their group after reconstruction elsewhere required redo surgery, and at the time of that surgery 26% had introital stenosis, 20% had a retained vaginal septum, and 13% had a remnant rectovestibular fistula. Late vaginal stenosis and obstructed menstruation occurred in 36% to 41% of patients (Breech, 2010; Hall et al., 1985). Warne et al. (2003) noted the vagina to be adequate for intercourse in 44%. Revision vaginoplasty is often needed. Normal menstruation was noted in only 35% long term. Additional treatment was needed in 38% for obstructive hematometra (Versteegh et al., 2013). In Rintala's own patients, 19% were found to have large cystic collections related to the uteri or adnexal tubes that required surgery (Rintala, 2016). These were not related to obstruction. Although reports are limited, it appears that the majority of reconstructed patients are capable of normal sexual life. Pregnancies have been achieved spontaneously and with in-vitro fertilization in patients with reconstructed cloacal anomalies. There is an increased risk for preterm labor, and cesarean section is the preferred mode of delivery (Vilanova-Sanchez et al., 2019).

Although not a direct result of reparative surgery, renal outcomes are worrisome. Renal insufficiency was found in 50% of the patients treated at Great Ormond Street Children's Hospital, and 17% of the patients progressed to end-stage renal failure (Warne et al., 2002a). In the series of Rink et al. (2005b), 18% had an abnormally elevated serum creatinine level, and in another 26% it was borderline. Lifelong yearly urologic evaluation is warranted, and prompt recognition plus treatment of any obstructive pathologic process or urinary tract infection is imperative. Bladder dynamics must be evaluated and abnormalities addressed. Of 24 reported adult patients, 17 had coitus and 6 had borne children (five cesarean deliveries and one vaginal delivery) (Hendren, 1998).

Leclair et al. (2007) reported on cloacal repair using the TUM technique. Urethral stenosis occurred in 2 of 22 patients, and both required a Mitrofanoff catheterizable channel. One child developed a urethrovaginal fistula, and three had vaginal stenosis. Continence was noted in 15 of 17 patients older than 4 years of age. Seven patients voided spontaneously, and 8 emptied by CIC. Fecal continence was present in 12 patients, with 9 having spontaneous bowel movements and 3 requiring MACE irrigations.

Summary

Management of urogenital sinus and cloacal anomalies can be exceedingly complex. In children with DSD, prompt but very careful evaluation by an expert multidisciplinary team is mandatory. Family support and education with openness and respect for the child and family are required. Differing cultural practices must also be respected and accepted. Confidentiality must be maintained. Regardless of patient age, surgical reconstruction requires great care of tissues, meticulous attention to detail, and a lifelong commitment by the surgeon. These complex anomalies require an entire team of physicians and nurses dedicated to the care of these problems. Urogenital sinus and cloacal anomalies are very challenging reconstructive problems. Those patients at the more severe end of the spectrum should be handled only in centers with great expertise and experience.

Adolescent and Transitional Urology

Dan Wood PhD

There have been significant developments in urology and transition, but we are relatively backward when compared with other specialties. For example, oncology and rheumatology have really recognized the need for and benefits of transitional care as a means to improve lifelong care and outcomes. They appear to have a much more consistent approach (Clemente et al., 2017; Crowley et al., 2011).

This chapter will explore some of the models of transition and the reasons why lifelong care is important in some of the conditions that we treat on a regular basis.

The essence of transition is allowing a young adult to assume a central role in their own health care. The majority of the patients we deal with have a congenital anomaly discovered at birth and managed from infancy to the present day by a (largely) consistent pediatric team. For the early years, necessity dictates that parents make many decisions for the child in keeping with advice from pediatric urologists. There are a variety of views on healthy (or not) parental involvement, particularly in adolescence. **It is consistently true that children grow up, even when faced with major congenital anomalies and the major treatments (surgical or otherwise) that these will lead to. Thus the child, adolescent, and later adult need to be at the center of these decisions.** This goes without saying and is reflected in much of the practice we see; arguably the most difficult time to achieve this is during adolescence. There are a variety of reasons behind this:

1. **The developing adolescent brain does not always see the risks or consequences that may follow some behaviors.** This can translate as a young adult patient deciding not to continue (or undertake) some important elements of treatment as they attempt to exert their independence and authority in the world. This can be misguided and

dangerous, which reinforces protective behaviors in both parents and health care workers.

2. Parents are naturally protective of their child, and although some are very good at stepping back and allowing their child room to grow into their independence, others really struggle with it. Watching their child make big treatment decisions or sign consent forms for the first time while being encouraged to sit on their hands and keep their mouth shut must be incredibly difficult, especially when they have taken such a significant role in their child's health care to that point. Sympathy for the patient is further evoked by the so-called adolescent behavior outlined in number 1. In this context, we are imploring parents to step back.
3. Pediatric practitioners have developed a strong mutual bond with their patients (and parents). Handing any patient on to another team is difficult for any doctor for all sorts of reasons. Pediatric urologists are as subject to this as any other; they need to know that their patients will remain in safe hands and that they will be allowed to learn of their long-term outcomes.

The understanding that these patients need care in adulthood was a major step forward; the further leap was to understand that the “qualifications” for providing that care in adult patients were not fully covered in either a conventional pediatric or an adult urology training, and thus a hybrid practitioner was needed. The concept of an adolescent urologist and with that congenital lifelong urology has become a growing reality. It has been applied in a variety of different ways. Most importantly is the fact that major intervention in childhood is the beginning of a contract between the health care system and that child. Somehow the system has to offer a design that will treat the initial diagnosis and then provide necessary care for the rest of the patients' lives. This may be achieved in a number of different ways, none of which is absolutely right or wrong. But care in silos (pediatric and adult urology) does not deliver what these patients need; there has to be a productive interaction between both and the provision of lifelong care where it is needed (Wood, 2014).

Definitions

Transition

The American Academy of Pediatrics (AAP), American Academy of Family Physicians, American College of Physicians, and American Society of Internal Medicine have mandated that “all adolescents with special healthcare needs should have a written healthcare transition plan by the age of 14 years” (AAP et al., 1996). **The adopted definition of transition is “the purposeful, planned movement of adolescents and young adults with chronic physical and medical conditions from child centered to adult-oriented health care systems”** (Rosen et al., 2003).

Although the author understands these definitions, it is his belief that they are both lacking. Both could be interpreted as the system being active while the patient remains the passive recipient of transition. Working in an adolescent/adult environment and looking after such urologic patients “after” their pediatric care highlights the importance of pediatric teams needing to prepare patients for an active role in their health care and the understanding that they will not be in a children's hospital forever. This is in no way underestimating the challenge of this.

Greater than 90% of children with chronic conditions expect to live into adulthood. The morbidity during transfer from pediatric to adult care is high. In cystic fibrosis, there is a peak of deaths in the adolescent and young adult period.

Too often there is focus on the transfer; good preparation of a child for transition takes years.

The essence is to begin conversations with both the child at an early age (maybe 10 or 11 years) and parent(s) that begins to get the child to write down or details his or her own diagnosis and needs both in health care and, perhaps, more widely. Making children central in this and building their confidence to participate will activate them and help to reassure parents of their capability. Gradually, the child becomes more and more active in his or her health care and ultimately is ready to take full control; ideally it should be the child in conjunction with the health care team that devises the aforementioned plan. The introduction of the adolescent team can be judged (balancing the local system setup with the individual patient needs) but is an important stage in the process.

Ideally, the new team should try to meet the patient and the parents in an environment that is familiar for the patient. The move to another center can follow. At least this incorporates a familiar face or two when the patient does move.

There is a range of reasons why conversations and indeed both transition and transfer may be delayed. Most importantly is the readiness of the child and family. This may be in medical, surgical, or psychological terms. The pediatric team needs to make that judgment, but if transition becomes part of normal parlance and therefore a realistic expectation for both the patient and their family, it may have a positive impact.

The aim of a transition program should include structure and principles that bring information and readiness into a single stream (Cooley, 2013) (Table 50.1). Having information that a patient can access would be useful. Whenever and wherever they seek medical attention, they will be able to share important and relevant medical details with the local team. The most rudimentary for this would be a paper health passport that the patient could write in and retain copies of correspondence from their health care team(s) within. Web portals through the Internet or smartphone apps may become the method of the future. There are examples around, but there has not yet been widespread uptake.

TABLE 50.1

Six Core Elements of Health Care Transition

ELEMENT	DESCRIPTION
Transition policy	Written policy that can be shared with parents, patients, and staff
Patient registry	System for registering and tracking young adults through the transition process
Preparation	Process for assessing readiness for self-care management and adult care
Transition	Written plan including actions needed, medical summary, contact details, and emergency plan
Transition and transfer	Implementation of adult care model and move to adult provider
Transition completion	Explicit end to transition and an assessment of outcome

Data from Cooley WC. Adolescent health care transition in transition. *JAMA Pediatr* 167(10):897–899, 2013.

Failure of Transition

If we are to devote chapters, energy, and medical careers to the area of adolescent, lifelong care and transition, we ought to ask what it looks like and what we should do when it fails.

Transition may fail for a variety of reasons:

1. Crossing an age threshold in a pediatric center and having nowhere to go
2. A patient deciding he or she no longer wants to engage with health care
3. Changing circumstances (e.g., moving out of the area)
4. A patient deciding he or she does not want to go to the “new” center

The least ideal is number 1; in all other scenarios, patients can be given information about how to reach out to a center equipped to help them if they wish to. In all scenarios, patients can be given medical information about themselves to ensure that, when they arrive at another center, they can at least give the background information, including who the receiving team could contact for additional information if necessary.

Data from Indiana suggest a reduction in the need to attend an emergency department in patients who are engaged in transition and long-term care (Szymanski et al., 2017). We know from groups looking after oncology and diabetes patients that **health care outcomes seem to be improved with a good transition service.**

The challenge, in our own specialty, is to offer metrics that can quantify this. We all clearly understand the need to safely monitor these patients for their potential complications and, where possible, to avoid them needing to seek emergency care. But there are an increasing number of centers adopting a more formalized approach to transition in urology (Lambert, 2015).

Transition is a purposeful process that involves preparing and screening a family and patient to ensure everything is in place for a transfer event.

Transfer

Transfer is the move of care. This can be both geographic and a change in personnel. The combination of this and available options will play a key part in the model of transition that is used. The importance of this relates mainly to infrastructure and therefore deserves relatively little coverage here. The need for mention is to ensure that transfer is distinguished from transition. Transfer is often part of the process, but the two elements are distinct.

Models for Transition

As part of a recent consultation, it is apparent that, globally, there are four potential models for transition. There are no data to support one model over another, and the development of a local system will be driven by local infrastructure, practice patterns, enthusiasm, and resource.

There is no defined or optimal age for transition. **Ideally there would be an age window that allows pediatric teams to make a judgment about the right time to transition a patient to the adolescent/adult team.** Preparation and a degree of flexibility allow health care professionals to make judgments around areas such as medical fitness, surgical concerns, emotional maturity, and support from family members. It is also important to assess the understanding of the patients themselves related to their diagnosis and treatment. These are all factors that would appear to influence transition and its likely success; the idea that it should be a gradual process rather than a sudden, age-defined event seems to be accepted.

There has been very little work to examine these factors or their relationship to success. This is a problem when trying to justify a service, particularly in a resource-limited environment. Increasing the number of appointments allowing introduction of the adult team in the pediatric setting may improve engagement with transition. Those who have successfully transitioned are less likely to attend an emergency department (12% to 14% vs. 75%) (Szymanski et al., 2017).

Lifelong care from a pediatric urologist:

1. When a pediatric urologist works in a combined pediatric/adult urology department:

    This model has two potential advantages. First, the pediatric urologist offers absolute continuity, that is, there is no transfer from one unit or doctor to another. This alleviates one aspect of concern for patients and parents. It also allows a pediatric urologist to follow his or her results throughout his or her career, a very direct form of feedback, although risking personal bias. Surgically, the pediatric urologist will need to have had sufficient training in adult reconstruction; other subspecialists including stones and endourology, andrology, and oncology will be available and important. This model allows adult urologists to understand the pediatric aspects of care and vice-versa. The colocation should also facilitate joint clinic consultations and operating.

It remains a fact that the pediatric urologist's career will be shorter than the lifelong care required for the vast majority of patients. Therefore, at some point, these patients (who will have formed an enormous bond with their surgeon) will have to move to a new doctor. This may be more easily managed in later life (for the patient) as opposed to adolescence; there is no evidence that one is better than another, but it is important to consider. There is some evidence to suggest that continuing care in a purely pediatric environment is not healthy for either the specified patient or other surrounding (pediatric) patients (Jesus et al., 2014).

2. When the pediatric urologist integrates with the (separate) adult urology department:

    This model also offers continuity from the pediatric urologist and allows him or her to work collaboratively with adult urologists and transfer elements of (or all) care as appropriate. Awareness of and willingness to use surrounding expertise are important for success.

    Multidisciplinary care for these patients is essential throughout life. The pediatric urologist will need to form links with adult specialists, including nephrologists, radiologists, endocrinologists and gynecologists. This is possible and has been done but cannot be ignored.

3. Transition from the pediatric urologist to an adolescent/adult specialist with an interest in this area:

    There must be a local, interested, and appropriately trained adult urologist. It is vital that he or she has a background that includes experience with complex pediatric urology and adult urologic reconstruction. This urologist will often act not only as a doctor and surgeon to patients but will often coordinate other aspects of a patient's care with other members of the multidisciplinary team (Bower et al., 2017; Szymanski et al., 2015).

    Preparation for transition and the management of transfer are important. The pediatric team needs to prepare patients and parents for this phase of their care. There needs to be a mutual trust between teams to allow the standard of care to be maintained. A joint clinic is very helpful, and clear communication with the patient is vital. Not all agree but allowing patients to meet their new (adult) carers in the pediatric environment that is familiar to the patient may offer some benefit in terms of knowing who they will meet once transferred and agreeing on a plan (Timberlake et al., 2015; Woodhouse, 2015).

4. Direct transfer from the pediatric urologist to adult urology:

   This model may not involve a transition plan or a managed transfer. Some health care systems have been slower to recognize the need for transition, creating a risk that patients may become invisible to health care and only present with problems and emergencies. If (and sadly when) this happens, it demonstrates the need for appropriate expertise in managing these patients who can have very complex needs.

   Ironically, patients unwittingly may introduce this for themselves. As they grow, they head off to university or work in another city or country. They may not wish or be able to travel and see their original urologist, and it can be difficult to find a comparable level of expertise for them, leading them to drop out of necessary follow-up and only present if a crisis occurs (Wood et al., 2019).

Patient Population

Adolescent patients will enter a service based around adolescents and urology in four potential ways:

1. Transition and referral from pediatric service (see previous section)
2. Referral from pediatric services without transition
3. Referral with new problems arising in adolescence
4. Emergency referral having fallen out of pediatric care.

Clearly, there is room for crossover between these groups. As a matter of principal, we should aim to pass all patients with a long-term condition who will require care in adult life through transition.

Ideally, all patients would exist in groups 1 and 3; for a variety of reasons, they do not. Although there is increasing recognition that transition is important as part of continuing care, it is far from universal. In some systems, group 4 is far more prevalent; it may be much harder for patients to obtain health care once they are no longer dependent on their parents as a result of having a preexisting condition.

Group 2 is also less than ideal. Although a pediatric team has referred the patient on, the lack of transition infers a lack of joint working and cross-team engagement.

Setting Up a Service

Training

Pediatric urologists have increasingly acted as advocates on behalf of their patients. In many areas, it is they who have highlighted the need for long-term care of their older patients. The problem has been engaging adult practitioners to take the work on. As stated in the introduction, training in general adult urology or pediatric urology will not cover some aspects of this care. It requires someone who can work in adult practice (as the majority of patients will be adults). **They must understand both the pediatric diagnosis and treatment. As part of their adult role, they must have a strong reconstructive background.** As yet, there is no formal program in any system to train the adolescent/transitional urologist.

The Multidisciplinary Team

As a urologist looking after patients with congenital anomalies, the individual and those around need to shape a multidisciplinary team around them. This is a subspecialist role, and thus adolescent urologists are likely to have a focused portfolio of surgical skills. They need to work in a group of individuals who have skills that compliment their own. This will allow cross-referral and colleague involvement when necessary. These will be complex cases, so whatever surgery is done, it is not for the occasionalist.

Outside urology (nephrology, gynecology, and radiology) are vital. Colorectal surgery can be extremely valuable along with endocrinology, genetics, psychology, and a consistent anesthetist.

Patients have many concerns and, at times, needs. These include anger at their diagnosis and sometimes at their treatment; issues around normality; and concerns about aspects of function including sexual function and at times sexuality. This rather amateur (surgical) summary emphasizes the importance of a psychologist. These can be easier to involve in some areas than in others, and resistance for them may come from our paymasters as they often do not bring in additional income. In management terms, this makes them a net cost. Thus, from a clinical and patient perspective, there is a clear justification; however, financially the cost has to be argued for.

Institutional and Political Support

There is increasing understanding of the value around transition to both patients and institutions. There are many reasons why. There is now good evidence to support the personal and financial impact of failed transition. **Patients with complicated childhood medical problems are highly likely to access health care in later life.** They are more likely to attend emergency departments if they are not part of an ongoing health care program (Szymanski et al., 2017). These attendances are expensive and are more likely to signify a crisis. Robust ongoing care reduces the risk for both the crisis and the emergency department attendance.

There is a drive for multidisciplinary care across the health care sector. Patients who attend a general urology clinic where there has been no transition are unlikely to receive the desired multidisciplinary input. These patients may be medically, psychologically, and socially vulnerable. Access to all three aspects is important to maintain an effective standard of care.

The drive for a transition service will come from the clinical teams. The fact that there is widespread recognition of its importance should help with establishing a momentum. It remains unlikely that managers in any setting are going to invite you to set up a service. It is likely that you will have to justify your cause alongside any other group or service. The current discussion and political environment should help.

Barriers to Transition

Institutional

The previous section illustrates the reasons why a service is important and should be established. Health care is a resource-limited environment; therefore those trying to initiate a service will encounter challenges and resistance.

Whether a transition service makes money (or not) for an institution depends entirely on the remuneration related to your service. The health care system is largely defined for most of us. Whether we work in a fee-per-service or nationalized system, patients have similar needs.

The logistic elements of care are essential: a room to see patients in, operating theaters, and personnel. These will be harder to argue for if your service is unlikely to profit your organization. Building a team comes down to individual engagement; whoever has the idea (usually the urologist) will need to seek out and acquire the expertise needed and engage those needed.

Children and adolescents with unmet health care needs are much more likely to attend clinics and emergency rooms. Establishing a good transition program demonstrates its worth by reducing (costly) emergency admissions and the rate of in-hospital transfers. This has been shown in urology but translates from other specialties too (Okumura et al., 2014; Szymanski et al., 2017).

Professional

Pediatric care is often centralized and multidisciplinary; adult care can be more fragmented. Adult care tends to be more subspecialty focused.

As an adolescent urologist, it is reasonable that your pediatric colleagues (your referrers) have to trust you and your service. Without their referrals, you have no work. This may be difficult at times. For example, you will wish to publish your work. This is important as it will guide present and future practice. **Honest data will acknowledge the successes and recognize complications.** There will be some controversies; in order to maintain credibility, it is important to try and understand the denominator, maintain an objective view of the patient and their treatment, recognize that these patients are complex for all and there may be limits to what is achievable. If appropriate, publish in collaboration with pediatric colleagues.

Immediate colleagues in an adult department may struggle with the content of an adolescent practice. Congenital patients are often complex. Surgery may lead to complications, and the workload will appear very different to those who principally undertake primary rather than revision surgery. Others may know the diagnosis but are unlikely to understand the full implications of that diagnosis and are, for the most part, unfamiliar with the treatment a patient has undergone.

These are rare diagnoses treated in specialist centers, thus it is neither surprising nor critical that these problems occur, but they will create some difficult conversations with colleagues who do not absorb the full extent of your work. These will come to the forefront when you discuss reasons behind patients needing more bed days than others. Most doctors are used to working within a protocol or a guideline. Many have an index diagnosis or case on which to gauge their outcomes. In this field, the diagnoses are rare and treatment often complex’ this means that although a set of principles exists, the practical application will vary with each case. It is ideal to collaborate with colleagues when appropriate but also work hard to ensure that all team members understand what is happening for an individual patient.

Patients

The adolescent brain is constantly undergoing a rewiring process. The positive aspect of this is the potential to develop independence. The negative impact is an increased tendency to expose themselves to risk without considering the consequences (Arain et al., 2013).

Many of these patients will need long-term care (and if they do not, that is a specialist decision in itself). Good medical care may help patients achieve some elements of normality that are difficult and in some cases more dangerous without medical support. An important example is pregnancy and childbirth. **Ensuring a multidisciplinary team around a patient allows the safe and certain diagnosis of pregnancy** (remembering the risk for false-positive urine pregnancy tests with cytoplasm), preservation of renal function throughout the pregnancy, and a safe decision and support for the delivery of the child. Although this does medicalize a pregnancy, it does ensure that the pregnancy is both possible and safe. Even the explanation that this is possible can be valuable to patients.

This group have a completely normal desire to be normal (Wilson et al., 2004)**; even an annual visit to hospital marks them as different from their**

peers. One part of transition is the loss or change of at least some of their health care team. A patient will ask questions about their relationship with normality and what he or she can achieve. At a time when every adolescent is establishing independence, they may push against frameworks that seem to be taking control away from them; this leads to clashes. A sudden change in behavior may center around stopping important elements of care, such as medication, catheterization, or washouts. Some may withdraw from their health care altogether.

One of the aims of transition should be to support patients through this. Engagement and information are key. Trying to work with the individual patient can be difficult, so allowing them to explain themselves and making it clear that the bond is primarily with them and not their parents are important elements. There is a balance between encouraging patients to undertake the important parts of their own care, ask questions, or challenge what they are concerned about while avoiding confrontation unless completely necessary.

If this relationship breaks down (for whatever reason) patients are at risk for becoming a barrier to their own transition and therefore appropriate health care.

Expanding Numbers and Management of the Service Long-Term

The work delivered by an adolescent and adult service looking after the long-term care of pediatric patients can only expand. In service planning and modeling, this is an important factor. It is important to consider how a service works for a patient, too. In a specialist, centralized service, there will be a need for many patients to travel considerable distances to see a doctor in that center. The solution to these problems does not necessarily mean more medical staff in a central institution. Other options should be explored. For instance, the increased use of remote clinics using telephones or more advanced telemedicine may make efficient use of a medical team's time, allow an appropriate review for some patients, and reduce the need for them to travel for every visit.

If there are interested clinicians in other centers, it would be ideal to foster this interest. Other centers may not have the resources to run a full multidisciplinary team. This should not exclude clinicians from working in this area. They should be encouraged to work collaboratively, sending patients in for review when necessary and if possible following their patient so continuity is maintained.

There is necessity for lifelong review for some groups—most of those who have had major surgery or have some form of persistent renal impairment. In other groups, we may be able to be more selective in follow-up as long as patients know they have a center they can return to. The author's center had historically maintained follow-up of all adult posterior urethral valve patients. Anecdotally, this is changing. There is certainly a group of young adult men whose outcome seems to be favorable, and the approach is changing. They will be followed up through university or into their early twenties, and if all remains well they can be discharged.

There needs to be a central focus around which a multidisciplinary team is built. Although the numeric challenge may seem like a barrier, if acknowledged and managed well, it may serve to improve the service and the care of individual patients. Other centers and clinicians can contribute to this; this will expand interest in the specialty, improve access for patients, and help manage the expanding workload.

The Importance of Specialist Nurses

Good specialist nurses are invaluable to the service and patients. A well-trained, experienced specialist nurse adds a huge amount of expertise to the team. They can readily perform assessments and investigations for patients. They are generally much better than doctors at informing patients carefully of the direct implications of a planned procedure. They will take time and give an in-depth view rather than the rapid overview that a doctor will tend to give. Information for patients is better given in multiple forms in complex situations (Wong et al., 2010).

Anecdotally, nurses are not only very effective at giving information, but patients are often more ready to share information about their care with specialist nurses. In assessing the complex patient, this is very useful. For all of these reasons, they make a very valuable contribution to the multidisciplinary team. They may confirm or occasionally alter the course of a patient's management, picking up important warning signs.

Specialist nurses are vital to transition. The reasons detailed earlier apply—the giving and receipt of information. It is not common, but it is significant when issues around vulnerability and child protection arise. Our nurses have been exceptional at the recognition and management of these situations. They are a positive asset in reinforcing, informing, delivering, and coordinating care in the new environment (Ferguson, 2010).

Clinical Delivery

Geography

As described in the Models for Transition section earlier in this chapter, the location of the service is important, but no one setting defines the likelihood of success. Many confuse *transfer*, the change of team and (possibly) location, with *transition.* As defined earlier, transition relates to the assumption of the patient's role in his or her care. It is important to explain that care in an adult setting will feel different, simply because it is aimed at adults and not children. When patients and parents are faced with the reality of this, they can find it difficult to adjust. The presence of familiar faces and careful overall management are the only ways to overcome this. It does take time and can lead to some difficulties as part of overall transition.

The Clinic

The clinic needs to be regular and set in an appropriate environment. At the outset, there is value in the joint meeting among the patient, his or her pediatric team, and the “new” adult team. There needs to be a big enough room to accommodate the staff required. There should also be a balance to ensure that patients are not overwhelmed by health care professionals in the room.

Patient/Parent Preparation for Transition

It is easy to forget the fact that any patient transitions from a pediatric service to adult care is a success. We now take for granted that children with major congenital anomalies will survive into adulthood. This is a result of developments in surgery and the surrounding care. Yet the point at which the move is made to adult services can feel like bereavement. This is understandable and is the result of the strong bonds that are formed among a health care team, the patient, and the parents.

This sudden wrench surely contributes to the negative feelings that are associated with this change. Many other factors are included in this chapter, some which can be controlled; others cannot. **We cannot change the fact that for all patients, there will be a change in health care provider at some point.** There is some logic in making that change when the need for adult care arises and thus preparation is important (Bower et al., 2017).

The gradual introduction of the need for transition is the logical way to undertake this. Initially the pediatric team begins to discuss with the patient and the parents information about the diagnosis and treatment. The idea is to steadily increase the amount of independence a child has in his or her own health care. As independence increases, the idea that his or her health care will need to continue but in the adult world can be introduced. As these ideas become part of the same trajectory, the introduction of the adult team for joint meetings becomes appropriate. **The investment made by both sides is important; the fact that the pediatric team shows trust and collaboration with the adult team will help engender trust and cooperation from the patient.** The ability of patients to understand and discuss their diagnosis and treatment will empower them within this whole process and give them a genuine voice that influences their care. This will also make the process less traumatic for them because they continue to maintain control.

What Does Success Look Like?

There are published data to show that **the early years following transition appear to be a high-risk time.** Clinical issues seem to arise frequently around this time; 56% of patients with urologic issues required surgical treatment, and in the United States 50% will have issues with insurance coverage that interferes with their care (Duplisea et al., 2016).

It would be difficult to choose a clinical metric that would apply across the board in urology to measure success in transition. Quality of life measures are also a poor indicator of medical success in complex patients and lack specificity for these patients. We are left with looking at how these patients engage with health care. Do they attend? Does their attendance reduce the need for emergency admissions? There are some data from Indiana that support these principals. As previously discussed, other specialties (diabetes, rheumatology, and respiratory specialists) have suggested improved health outcomes as a result of engagement.

The evidence is thin but broadly supportive of engaging patients and their parents in transition with a focused team and ensuring that there is a credible plan for their long-term care.

The Price of Failure

Many of these patients will have abnormal parameters in some form such as anatomy, baseline renal function, fertility, or chronic pain. Medical deterioration may be gradual and subtle. It may be predictable in some but not in others. Identifying this and understanding what needs to be done requires a combination of expertise (Woodhouse et al., 2012).

Therefore, many of these patients will require multidisciplinary health care, some elements of which can only be delivered in a specialist center. It is the availability and the dialogue within that team that goes to creating the best care. It may be that some elements can be achieved off-site, but the dialogue and direct contribution to the team risks diminution (Woodhouse, 2012).

If this dialogue is lost, subtle changes may be missed and opportunities to prevent further damage delayed or lost.

Therefore, **the price of failure is (most commonly) preventable loss of function.** It would be wrong to say that a specialist team will always prevent such loss; it may not, as some will be inevitable. But appropriate transition may be able to slow loss of function, offer alternatives, and support patients when loss occurs. It is important that the patient is assured and knows that these situations arise because they were inevitable and not because expertise was lacking.

Key Points

- Transition is the development of a young adult's understanding of and independence in their health care.
- Preparation for transition can occur over a number of years.
- A multidisciplinary team is essential in both pediatric and adult care.
- There are a variety of models for delivering transition and adolescent care; these vary depending on the health care system.
- Those caring for adult patients with complex congenital anomalies must be trained in both pediatric and adult reconstructive urology.

Clinical Practice: Major Diagnoses

Functional Assessment of the Reconstructed Urinary Tract

There are few data published about how to assess the reconstructed urinary tract. Many of these patients have a range of things that move them away from a "normal" range. There are some parameters that need to be maintained, such as bladder pressures.

Other measurements are altered by a variety of factors; these include the original diagnosis, the treatment, and changes in puberty.

Video-Urodynamics

Video-urodynamics is a commonly used and vital tool that can be used in a variety of ways. With a new technique, it can be used to establish part of the outcome and safety, but it has a significant application in regular practice. The major indications are assessment of continence (or incontinence), especially in the face of change, and assessment of the urinary tract with deterioration in renal function (Fig. 50.1).

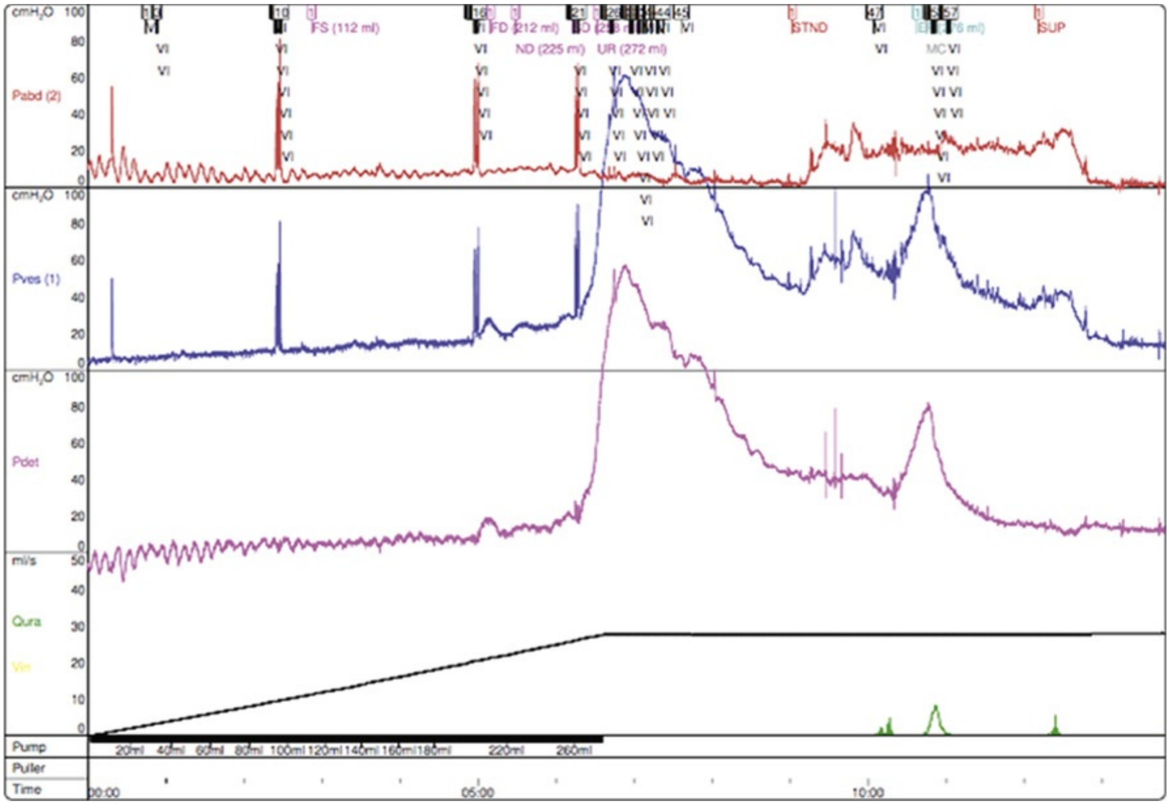

FIG. 50.1 Urodynamic tracing from a 20-year-old man with a neurogenic bladder. Note the significant detrusor overactivity after the end of filling.

Video-urodynamics is also useful in assessing the anatomy of the urinary tract. Examples include assessment of the ureters and reflux, the appearance of the bladder (can be useful with a native bladder in the presence of a diverticulum), the anatomy, and sometimes the type of bladder reconstruction. The bladder neck and (with careful views) the urethra can be assessed; this can help with assessment of a stricture, surgery, and fistula, both congenital and iatrogenic.

Flow Rates

Flow rates are a common reading that we take in any adult urology clinic. We understand what is normal in a 60-year-old male patient with lower urinary tract symptoms. There are much fewer data to tell us what is normal in a reconstructed or congenitally abnormal urethra. We know that many patients will have lower urinary tract symptoms, and there is little we have to alter those. We can attempt improvement with medical (and sometimes surgical) management, but it is common for some symptoms to persist.

Flow rates can be useful for monitoring change, including the flow itself, bladder volume, and postvoid residual. There are some published data suggesting that the flow rate is commonly low (Piplani et al., 2018; Spinoit and Hoebeke, 2015), but the individual patient will guide you much more than these on the basis of change in measured flow rate and symptoms such as pain and urinary tract infections.

Renography

Like other investigations, renography and nuclear medicine have their place. It is often something that can be used to clarify change in drainage or split function. It is rarely used as a primary follow-up investigation but is usually indicated if there is a change in measured renal function, new or progressive hydronephrosis, and/or loin pain.

Ultrasonography

This is a mainstay of long-term follow-up and often recommended for exactly that as they are noninvasive and require no radiation. Whether performed by the overseeing team themselves or a radiologist, the ultrasound operator must have an understanding of the clinical situation and anatomy. If the operator is not regularly looking after patients of this sort, your direct involvement may be necessary.

There are, of course, limitations, in particular the ability to detect stones. This is a balance. These patients will need review (usually with a scan) on an annual basis. The scan used must give good information but be balanced against any other risks to the patient (e.g., excessive ionizing radiation).

There are some useful determining factors. In the case of potential bladder stones or bladder wall lesions, asking the patient to shift position and seeing whether the “lesion” moves will differentiate between mobile debris or a stone and something that is fixed to the bladder wall. A blood supply in the lesion will rule out a diverticulum, ureterocele, or bladder wall calcification. The bladder can be assessed to ensure that it empties completely.

The upper tracts are important to assess. Looking for lesions that look like stones is important, and you must be aware that renal sinus fat can appear similar to a stone. Looking at historical scans or for an acoustic shadow are clearly important. **As with pediatric scans, it is essential to have a bladder full and empty view.** If you are not performing the scan, you will need to ask for this specifically because not all radiologists or radiographers will understand the importance of this element of the scan. When a scan has been performed and reported by someone other than you, if new or progressive hydronephrosis is a feature it is vital to determine whether the kidneys were rescanned once the bladder had been emptied. If not, the scan should be repeated with this included. If the kidneys were newly dilated with the bladder empty, then a mercaptoacetyltriglycine (MAG3) renogram and voiding cystourethrography (VCUG) will need to follow.

Blood Tests

Many patients will require annual blood tests. For those with just a neurologic, primary bladder or infravesical diagnosis, an annual renal function is all that would be needed. If patients have had a cystoplasty, neobladder, ileal conduit, or ureterosigmoidostomy, they too will need their renal function checked in addition to a full blood count and chloride, bicarbonate, and vitamin B_{12} levels.

Hypospadias

There is a strong theme in this work centering around the impact of having a congenital anomaly that requires treatment. There is little to help us understand how much of the psychological impact relates to the condition itself, its treatment, or other factors. There is a tendency to negative appraisal of genital appearance, but this does not seem to consistently correlate with a negative impact on sexual function. There are divergent data about the psychological impact (Woodhouse and Christie, 2005).

Hypospadias is principally a ventral hypoplasia. The most easily visualized feature is the meatal position, but severity may be masked with other tissues being much thinner than normal. This may only become apparent at the time of surgery. In less severe forms (usually distal), long-term follow-up may be unnecessary, however, more severe forms are likely to need further intervention beyond puberty. The need for further surgery is hard to ascertain because many publications do not quote a denominator, revision surgery rates, or long-term follow-up. If there is no immediate complication, then most cases that require revision will become apparent in later life (Barbagli et al., 2012; De Win et al., 2012; Rynja et al., 2009).

These patients are more susceptible to lower urinary tract symptoms.

These can be very troublesome for the patient. Examples include postvoid dribbling (20% to 40%), spraying (40% to 50%), and downward deflection of the urinary stream (25%) later in life. More than one-third of patients state that they are unhappy with the function of their urinary tract in adulthood. Having a baseline and being able to monitor for change (e.g., in flow rate) allows an adolescent urologist to determine whether there is an objective change and therefore the need for intervention.

There is a lack of data relating specifically to erectile function. There may be anatomic issues such as residual or recurrent chordee. This may not have been fully assessed at the original surgery, there may be a differential in growth of the hypoplastic versus the normal tissues, or it may be attributable to scar tissue. Approximately one-fourth of patients are thought to have problems with erectile function in adolescence and adulthood. The basis behind this is difficult to explain. However, the effect on ejaculatory function is easier to understand, with postoperative scarring, an abnormal spongiosum, and the potential for other problems such as urethral diverticula; this results in reported issues in 37% of patients (Higuchi et al., 2016).

Infertility may also be encountered by these patients (this is more common in patients who have other, more complex associated anomalies); in patients with isolated hypospadias, it seems to be around 13% and is probably attributable to the anatomic concerns detailed earlier (Asklund et al., 2010).

Exstrophy

Long-Term Reconstructive Outcomes

There are different concerns that arise during adolescence and adulthood.

The functional concerns are urologic, sexual (genital), and reproductive. There are a range of data to examine these; all are from small series and are therefore difficult to interpret comprehensively, but they are what we have and so are important to include. There are cosmetic concerns, and these are discussed in subsequent sections.

Where it has been examined, these patients show strong resilience. Many have experiences with bullying, although severe examples of this are relatively few. Their focus is on being as normal as possible and treated in the same way as their peers. Coping strategies centered on controlling the way they revealed information and adaptive clothing, but there were no psychiatric or defined long-term psychological findings (Wilson et al., 2004, 2007).

Urologic

Several series have looked at this aspect, and the focus has long been to look at the lower urinary tract. This is where the condition is manifest so it is logical to look at it. **Historically, regardless of technique, the principle of reconstructing the lower urinary tract in exstrophy has been the creation of bladder with a fixed outlet resistant to allow continence.** There is a considerable range of interpretation of continence. The literature needs to be read carefully. The author would define continence as the ability to retain urine without leakage and void spontaneously or catheterize urethrally. Leakage is incontinence, and if a patient is emptying by anything other than spontaneous voiding or urethral catheterization, then he or she is dry rather than continent.

The single most important variable in achieving continence was success at the primary closure. If there was need for revision or a secondary procedure, then the likelihood of spontaneous voiding was zero. The published data show that up to 77% of patients are dry (Baird et al., 2005; Chan et al., 2001); 80% have had urinary diversion at a mean age of 11 years, and 50% to 70% have had either augmentation or substitution cystoplasty (Gupta et al., 2014).

Many have had successful reconstruction of the bladder neck that protects them from urethral leakage. In this study, 50% had their bladder neck closed. Therefore, there are a percentage who have had successful bladder neck reconstruction who despite this are unable to void spontaneously or catheterize urethrally. It is not clear from published data whether urinary diversion in these patients was placed as a "back-up" option in the hope that patients would void spontaneously but may need a Mitrofanoff channel for bladder access.

Anecdotally, some adult patients have small amounts of leakage. When asked, they find this acceptable and certainly do not want further surgery to correct this. It is beyond the scope of this chapter to discuss the outcomes relating to specific forms of augmentation or diversion. These patients have usually had multiple major (mean of 8 in female patients) operations by the time they reach adulthood. In the female population, 19% suffered urinary incontinence as adults (Deans et al., 2012). They are likely to need more surgical intervention. This is not (usually) a result of their underlying disorder but the consequences of their surgery. These are not a surgical failure but are a realistic outcome of major urologic reconstruction.

Revision rates for a Mitrofanoff procedure range from 9% to 75 % of cases (Suzer et al., 1997; Veeratterapillay et al., 2013). There is no time limit on how long any one channel will last. There are some that are problematic from the start for a variety of reasons, most commonly a short skin-level stenosis. There are some that never seem to give problems.

The congenital group of patients undoubtedly have these channels for the longest of all groups and appear to have to the lowest late revision rate of all (O'Connor et al., 2019).

Those with cystoplasties or bowel of any kind in their urinary tract require careful follow-up. **Imaging will look for anatomic anomalies such as stones. They are at risk for metabolic consequences (e.g., hyperchloremic metabolic acidosis or vitamin B_{12} deficiency), stones (3% to 40%), and most commonly urinary tract infection** (Biers et al., 2012). The involvement of specialist nurses and a supportive team are very important to support patients, minimize complications, and pick up problems when they arise. They also need to be monitored for the risk for malignancy. Enterocystoplasty is probably a factor. This is especially true if they smoke or have a renal transplant (or another reason for immunosuppression) (Higuchi et al., 2010; Smeulders and Woodhouse, 2001). The risk appears greatest with a ureterosigmoidostomy. There is no value in annual cystoscopy as tumors occur in screening intervals, but changes in symptoms such as hematuria, urinary tract infections, or pain should trigger appropriate investigation (Hamid et al., 2009).

Exstrophy patients are reported as having normal kidneys (DeMaria et al., 1980; O'Kelly et al., 2018). If they develop renal problems, it can only be regarded as a consequence of the surgery they have had. These patients need to be monitored carefully for this. Annual blood tests including renal function and ultrasonography are a minimum standard. Changes in renal function or new hydronephrosis will usually require a MAG3 renogram and possibly video-urodynamics.

Key Points

- Normal values in laboratory testing or imaging may not be helpful. It is important to establish a baseline and look for changes in investigations performed.
- Long-term data for hypospadias suggest a higher complication rate than previously thought.
- Patients with hypospadias need consideration regarding erectile function

and fertility.

- Annual cystoscopy for tumors in patients with a cystoplasty is not supported by evidence, as the tumor pick rate is low; it is more important to investigate new symptoms promptly.

Male

Penile Concerns and Management

In practical terms, this is one of the most common issues to be raised in caring for men born with exstrophy. Almost all exstrophy patients will have concerns about their sexual function; it is important for those caring for them to be prepared to raise and answer these questions when appropriate.

Magnetic resonance imaging (MRI) has established that, in exstrophy, the penis is shorter in length but has a greater girth than a typical unaffected male. The total corporeal length is 60% greater in normal men (16.1 cm vs. 10.1 cm in exstrophy). Most of this deficiency is in the pendulous part of the penis (12.3 cm for normals vs. 6.9 cm for exstrophy). The posterior penis shows no difference (3.9 cm vs. 3.2 cm). The mean corporeal diameter is 1.0 cm in normal men and 1.4 cm in exstrophy men (Silver et al., 1997). The Kelly procedure is well described, and there have been a number abstracts discussed at meetings. Peer-reviewed data are needed to understand whether this offers a long-term improvement.

Dorsal chordee is common, but the severity varies. Some men will find sexual intercourse impossible, and correction is therefore necessary (Fig. 50.2). For others, there may be a need to experiment with positions, but sexual intercourse is possible. If surgery is required, there is no cross-corporal circulation, which allows disassembly and rotation of the corpora to correct a chordee (Wood and Woodhouse 2011).

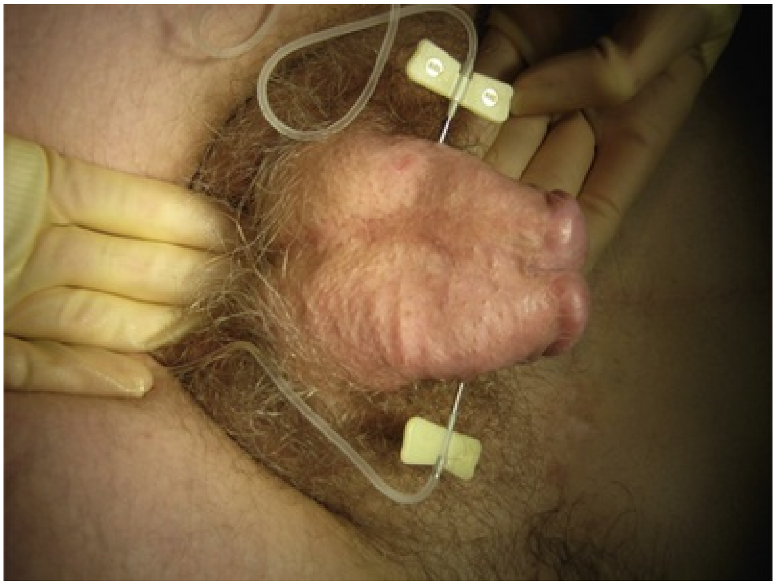

FIG. 50.2 Artificial erection demonstrating a dorsal chordee.

At birth the corpora are of equal size, but damage may occur during primary or revision reconstructive surgery (Fig. 50.3). Twenty-eight cases of complete or partial penile loss have been reported, 24 after exstrophy closure and 4 after radical penile reconstruction (Cervellione et al., 2010b).

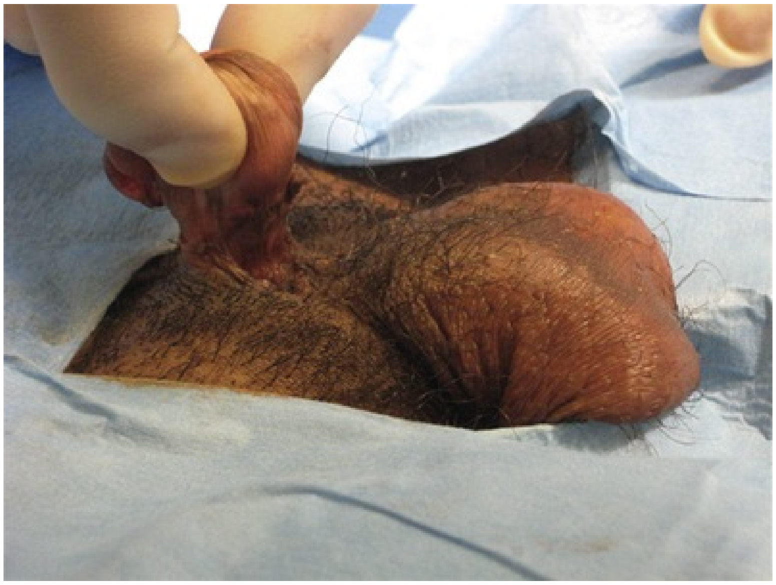

FIG. 50.3 Exstrophy penis showing severely damaged corpora.

Sexual Function

Erections can be expected to be of normal quality. However, in a comparison with normal men, 11 of 19 (58%) exstrophy patients had erectile dysfunction on the international index of erectile function-15 (IIEF-15), and the incidence in controls was 23% (Castagnetti et al., 2010). Other series report a negative impact on erectile function in up to 90% (Rubenwolf et al., 2016a).

Masturbation is virtually universal in all reported series. In a review of the literature from 1974 to 1997 including 134 men from eight series, 101 (75%) were able to ejaculate, occasionally producing as much as 5 mL. Some patients describe a more or less continuous urethral discharge of semenlike fluid (Hanna and Williams, 1972; Mesrobian et al., 1986; Silver et al., 1997).

Data from Switzerland looked at 21 male patients born between 1937 and 1968 with a mean age of 50 years at follow-up. Nineteen of 21 males were or had been sexually active, and 16 had been married. Only 56% described their intercourse as satisfactory. The main cause of dissatisfaction was the dorsal chordee (which nowadays would be corrected). Their adolescent sexual activity was similar to that of a survey of Swiss men from a later generation published in 2002 (Gobet et al., 2009). This is probably the longest available follow-up, but other groups give very similar figures, with about 75% of men cohabiting (Woodhouse, 1998).

Casual sex or the prospect of it may create considerable anxiety for adolescents with exstrophy. Boys with exstrophy are unlikely to be successful with “one night stands,” though patients reported by Ben-Chaim et al. were said to have random and short-term relationships (Ben-Chaim et al., 1996).

In a practice that focuses on transitional urology, there will be many discussions with patients about their genital anatomy. Chordee and other erectile deformities can be corrected, but there is no surgical means of producing the long, normal penis for which they hope. It is better to use knowledgeable and sympathetic counseling to help the adolescent establish a durable relationship in which normal sex takes place.

In extreme cases, phalloplasty may be an option for these patients. This was first reported in 2001 (De Fontaine et al., 2001). The native penis was incorporated within the new phallus with the glans and urethra emerging close to the base on the dorsum. A single inflatable prosthesis was inserted at a second operation. Other series have reported good satisfaction but high (50%) complication rates, particularly in relation to penile prosthetic implants (Lumen et al., 2008; Massanyi et al., 2013; Timsit et al., 2009).

Fertility

The testes are thought to be normal at birth in exstrophy. There may be an increased incidence of undescended testes, being reported in 6 of 26 neonates (23%). However, the structural integrity of the testes and epididymis suggests that the association is anatomic rather than endocrine in origin (Merksz and Tóth, 1990).

Data relating to semen parameters and fertility are sparse. In a literature review in 1998, including 66 adults who had had semen analyses for a variety of reasons, between one-third and one-half of men who were trying to father a child were successful, with only 21% having good-quality semen; 48% had azoospermia (Woodhouse, 1998). Other authors have echoed this showing poor semen parameters and low ejaculate volume (Ben-Chaim et al., 1996; Ebert et al., 2008; Rubenwolf et al., 2016a). Patients also report frequent episodes of epididymitis, which may be a description of the indurated feeling on palpation (Ebert et al., 2008).

The management of male factor infertility has been radically changed by the development of assisted fertility. Men with exstrophy can be greatly helped by these if they cannot conceive naturally (D'Hauwers et al., 2008).

Females Born With Exstrophy

Reconstruction of the Genitalia

It is important to understand the relevant anatomy for an adult female born with exstrophy. It is as if the urethra is on the abdominal wall, the vagina is just behind that, and the anus is where the vagina would be expected. Everything appears to have moved forward. They are often distressed by the dip in the region of their mons pubis and the gap in their pubic hair. **They may have a narrow introitus, which can make tampon use and penetrative sexual intercourse difficult and painful without surgical correction.**

The literature suggests that 80% of women will require genital reconstruction in puberty or early adult life (Mathews et al., 2003). The important features are to prevent introital stenosis, provide a hood for the clitoris, and fuse the anterior ends of the labia to make a fourchette. With complete soft tissue mobilization of the urogenital complex, especially if done in early childhood, it is possible to achieve a more anatomically correct outcome (Kropp and Cheng, 2000).

A narrow vaginal introitus is common in exstrophy; the vagina itself may be slightly shortened but of normal caliber and when the patient is standing the vagina is parallel to the floor. To open it, an incision is made posteriorly from the introitus until a sufficient opening has been created. It is usually possible to close the vaginal mucosa to the perineal skin directly. Cervellione et al. (2010a) describe a longitudinal incision of the vagina alone and laying in of a perineal flap. The results in all but 1 of their 29 cases were favorable regardless of the technique used, but they do not mention if any were having intercourse.

Procedentia Repair

The absence of a complete pelvic floor and the open pelvic ring makes the incidence of uterine prolapse very high in this group. Total procidentia may be seen even in nulliparous women (Woodhouse, 1999). The overall risk for prolapse sits between 38% and 52% with 85% deciding to have surgical treatment (Nakhal et al., 2012a; Rubenwolf et al., 2016b).

The restoration of a soft tissue hammock using the Kelly operation seems to show a significant reduction in prolapse. None of the nine patients who had a Kelly procedure had prolapse compared with two of three in the same series who had a different reconstruction. However, some of the patients were barely into puberty (Jarzebowski et al., 2009).

Several techniques have been reported for the repair of this difficult condition. Hohenfellner advocates fixation of the uterus to the anterior abdominal wall in childhood. This is said to prevent prolapse but still allow normal pregnancy with cesarean delivery (Stein et al., 1994). Once prolapse has occurred, anterior fixation does not appear to be an effective repair.

Although hysterectomy or partial hysterectomy has been advocated in occasional patients (Mathews et al., 2003), ideally the uterus is better preserved as it is the only “plug” that will prevent other pelvic and abdominal organs from prolapsing.

The most successful procedure is the Gor-Tex wrap. The sacral promontory is exposed. A strip of Gor-Tex is sutured or screwed to the periosteum. The end is passed around the cervix through the base of the broad ligament and brought back to the sacrum. This shows a success rate of 75% (Nakhal et al., 2012a).

Female Sexual Function

There are very few data looking specifically at this. The most recent data is the largest series (38 patients); using the Female Sexual Function Index suggested that there was little effect on overall sexual function (Rubenwolf et al., 2016b). Other earlier series cover 43 patients, but they represent only about 20% of the women recorded in the relevant institutions’ databases (Burbige et al., 1986; Mathews et al., 2003; Stein et al., 1994). Thirty-four (79%) had regular intercourse, and 10 of them had dyspareunia (29% of those having regular intercourse). The age of sexual debut is 19.9 years; 13 of 22 (59%) who were specifically asked had regular orgasms.

Fertility

Deans et al. (2012) reported that 4 of 19 patients achieved fertility naturally within 1 year, and the remainder were delayed or required fertility treatment. Rubenwolf et al. (2016) reported that the pregnancy rate after primary continence diversion was higher than after secondary diversion. Therefore, women with exstrophy do have some difficulties with conception that may be secondary to surgical reconstruction resulting in tubal damage.

Pregnancy and Delivery

Pregnancy is possible for these women. One report shows 57 pregnancies in 19 women with 21 miscarriages; this may be an overestimate as a result of false-positive pregnancy tests (associated with enterocystoplasty) (Nakhal et al., 2012b; Nethercliffe et al., 2001) but is greater than that expected in the unaffected population (Deans et al., 2012).

With modern obstetric care, pregnancy and delivery should be uncomplicated except for the risk for prolapse. Other series of patients including 43 pregnancies in 28 women were identified. Four ended in spontaneous abortion, and four ended in therapeutic abortion. There were 34 live births and 1 intrauterine death of twins (Greenwell et al., 2003; Mathews et al., 2003; Woodhouse, 1994). There is a high incidence of breech presentation at 57% compared with 4% in normal women (Greenwell et al., 2003).

The mode of delivery is clearly an obstetric decision, but a urologist should be involved in the management of the pregnancy to spot and treat urologic complications, which had an incidence of 63%. Delivery should be discussed, and emergency cesarean delivery should be avoided. This most commonly tends to lead to an elective caesarian delivery at approximately 37 weeks (Deans et al., 2012).

Spina Bifida: the Neuropathic Bladder

These are a challenging group of patients at any age. Their care needs to be multidisciplinary, and some will have complex needs. Many patients are fully mobile, and without knowing them, you would never know that they were affected by spina bifida. The spectrum of disability covers a huge range right through to those who are confined to a wheelchair with varying cognitive impairment. In caring for these patients, this becomes an important factor. These patients will have the same desires as their peers, including an education and the ability to work, form relationships, and have a family. These desires are shared by many patients with major congenital anomalies (Woodhouse et al., 2012).

In many, there is the ability to live independently and achieve these desires, however, others will need more support. Parents and family will often do an extraordinary job at this. **It can be enormously challenging to make judgements in some patients about their ability to make complex decisions.** They can be very emotionally labile and become very upset about conversations about complications. For those with impaired executive function, trying to gauge an understanding and make decisions about the right choice for a patient and the capacity for independent consent can be very difficult. Although parents may be very loving and supportive with only the best intentions, their support risks encouraging their son/daughter to undertake a procedure. Data suggest that surgery in this group is high risk, and thus the whole scenario needs to be judged very carefully. Some clinics run as a fully integrated multidisciplinary service with many agencies present. Not all institutions can or will support that way of working. Awareness in the clinician remains central to providing the best care (Szymanski et al., 2017).

Changes in Bladder Function and Continence

The bladder and outlet may change in their nature with time, particularly through puberty. It is also clear that patients themselves may well change their attitude to aspects of their care, especially during adolescence. Those who had been conscientious in performing regular self-catheterization may suddenly rebel. Their perspective is that they are “taking control.” This can be extremely dangerous, and may lead to unnecessary loss of renal function in a bladder in which pressure is a concern.

Renal and Urologic Concerns

Aggressive early bladder management combined with long-term follow-up have moved us past the time when renal failure was the primary cause of death for these patients (Malakounides et al., 2013). Great care needs to be taken as changing behavior of the bladder may damage renal function, especially through puberty and in combination with other factors such as urinary tract infections (Mundy et al., 1985; Woodhouse, 2005). Urodynamics are an important part of evaluating the urinary tract of these patients, and changes in continence or radiologic or measured changes in renal function should be assessed with video-urodynamics. These patients should be seen once per year with relevant blood tests and ultrasonography.

Proactive management continues into adulthood with the importance of regular catheterization regimes coupled with anticholinergic medication, botulinum toxin, and potentially enterocystoplasty when necessary.

Urinary continence is a major concern for these patients, and the severity of the incontinence has a significant impact on quality of life (Szymanski et al., 2018). Recent US data showed that 92.6% of adult spina bifida patients were using some form of bladder treatment; 76.8% needed to use intermittent catheterization, and up to 63% reported continence (Wiener et al., 2018).

These issues need to be raised proactively in clinic. Patients may feel embarrassed to discuss some subjects or may accept that this is the way things are going to be unless they are offered alternatives. They may choose not to take those alternatives, but they need to know their options; with the use of artificial sphincters, slings, and occasionally urinary diversion, patients do not need to be wet.

For those patients with fecal incontinence, it is important to either address this yourself or work with a colorectal colleague who can help you. Various systems exist, and the antegrade continence enema (ACE) works very well for children. Anecdotally, it is less successful in adults as the colon becomes more capacious. Per anal irrigation systems provide an excellent alternative. Occasionally a colostomy or ileostomy is necessary.

It is important to understand that operating on these patients in adult life carries a high potential morbidity. This should not prevent necessary or important surgery, but it should make all parties review very carefully whether surgery is the right option and what the alternatives may be. Up to 91.5% of adult spina bifida patients who have a laparotomy will have at least one complication; 40% will require further intervention (Clavien-Dindo 3 or 4) (Loftus et al., 2017).

Sex and Sexuality

Patients with spina bifida have normal desires to form relationships. Data suggest that although this is important to patients, it is often not discussed by health care providers. Published data have shown that this conversation is only had by physicians in one-third of cases (Bong and Rovner, 2007). Erectile function data vary widely with ranges from 40% to 75%. Those with a level below L3 seem to function normally. Above this level seems to make sensation and erectile and ejaculatory function less predictable, although erectile dysfunction is responsive to PDE5 inhibitors (Cassata et al., 2008). Some data suggest that azoospermia becomes more likely above the T10 level (Bong and Rovner, 2007; Choi et al., 2017; Palmer et al., 2000).

In females affected by spina bifida, L3 also seems to be a critical level, with those affected above that level having a significantly reduced frequency of orgasm (12.5% vs. 40%) (Cass et al., 1986).

Preparation for Pregnancy

For ladies growing up with any form of neural tube defect, it is important for a clinician to prompt a discussion around issues relating to pregnancy and preparation for it.

It is well documented that there is a higher incidence of neural tube defects in children of affected parents. This risk is halved with the use of high-dose folic acid supplements, which should be taken for 3 months before conception and throughout the first trimester (AAP, 1999). This conversation needs to take place and be documented for the sake of all parties, but most importantly the prospective mother.

If a patient has any form of bowel in his or her urinary tract, there is a 57% false-positive rate for urine pregnancy tests (Nethercliffe et al., 2001). This is probably caused by a contaminant in the mucous, but the exact mechanism has not been elucidated. The important point is that if a couple is trying to conceive and the woman has had urinary reconstruction with bowel, pregnancy should be confirmed with a serum hCG.

As with any other diagnosis, the pregnancy needs to be managed jointly between a urologist and an obstetrician. The discussion around delivery may be more weighted to a vaginal delivery if the pelvis is normal. There is a higher incidence of cesarean deliveries when compared with the unaffected population: 52.4% versus 31.9% (Shepard et al., 2018). Recent Canadian data have shown a higher incidence of morbidity to both the mother (intensive care admission, respiratory complications) and infant (hypoxia and intracranial hemorrhage) associated with pregnancy in spina bifida mothers resulting in prolonged hospital stay (Auger et al., 2019).

Posterior Urethral Valves

Posterior urethral valves causing subtrigonal obstruction affect approximately 1 in 5000 live male births. They have proven to be a significant long-term challenge (Heikkilä et al., 2011). Antenatal scanning has resulted in access to earlier diagnosis, although only 45% are diagnosed during pregnancy, and findings may be variable (Dinneen et al., 1993; Eckoldt et al., 2004). Understanding the pathophysiology explains the reason why long-term outcomes have not improved greatly despite improved diagnosis and some aggressive intervention.

The continued picture is one of approximately one-third of those born with valves needing a transplant, another one-third having chronic renal failure, and the remainder maintaining normal renal function. Those affected by renal failure appear to suffer the biggest impact on quality of life (Woodhouse et al., 2012).

Despite improved imaging and more aggressive techniques for early and even intrauterine intervention, the progression of the valve bladder and kidneys seems to be unchanged (Lambert, 2015). The valve bladder will hypertrophy and thicken, creating the classic appearance on antenatal ultrasonography with a blown-out prostatic fossa; this is a high-pressure, poorly compliant system that may ultimately decompensate and become unable to empty. The bladder pressure leads to upper tract damage and renal failure. The reason for the apparent lack of improvement in long-term outcomes may be that the kidneys are already damaged by the time the diagnosis is made, even with the in utero imaging that we have today. The child needs aggressive management, and the adolescent and adult will need long-term follow-up (Woodhouse et al., 2012).

In patients cared for by modern standards, 36.6% will progress to end-stage renal failure before they are 30 years of age. In fact, these data appear worse than previous cohorts, but this is probably because of the onset of antenatal ultrasonography and the ability to avoid fatal complications (such as sepsis) in early life with proactive early management. The data from Finland showed that 22.8% progressed to end-stage renal disease, with 32% of these patients progressing after adolescence, reinforcing the need to monitor these patients and work closely with a nephrologist to ensure optimal renal preservation (Heikkilä et al., 2011). Routine evaluation should include monitoring of renal function, blood pressure, and urine dipsticks for proteinuria (significant proteinuria is an important sign of progression of renal failure).

Data suggest that 36% of patients will continue to have issues with urinary incontinence beyond 5 years of age (Heikkilä et al., 2011). Others may have more minor but bothersome lower urinary tract symptoms. These need to be monitored and discussed during transition and continuing into adult life (Kovell et al., 2018).

Sexual Function and Fertility

It appears that erectile function and paternity rates in valve patients are not significantly different from unaffected males (Taskinen et al., 2012). The dilated prostatic fossa may result in retrograde ejaculation. Declining renal function is associated with erectile dysfunction, and this may affect some patients. Some data suggest an effect on semen parameters, such as a greater number of immotile sperm, longer liquefaction times, and intermittently reduced sperm counts (López Pereira et al., 2013; Puri et al., 2002).

Summary

In a book such as this one, adolescent urology or congenital lifelong urology will cross over with pediatric urology and elements of reconstructive urology. This chapter does not discuss every diagnosis that comes into an adolescent clinic, as much of the detail relating to these cases is found in other chapters. The aim has been to use some of the major diagnoses to highlight the principles of transition and the importance of long-term care.

Many patients who come to these clinics have had a lifelong relationship with hospitals and health care, and at times they may exhibit frustration. The ability to manage this frustration, broach subjects that others will not (as shown earlier), and understand conditions and care from pediatric practice are all essential components. Another characteristic of these patients is that, having seen doctors and nurses during their whole life, they very quickly pick up on those who are not as familiar and comfortable with their condition or care.

The increasing recognition of the need for a seamless link from pediatric care though adolescence and into adult care demonstrates the importance of this work to health care systems and, most of all, to patients. To undertake reconstructive surgery in anyone, but especially a child, creates a contract between that child and the system that provided that surgery. There will be a number of ways by which that system can provide care, but it must make provision for the lifelong care that child needs.

Key Points

- Congenital lifelong urology requires a proactive approach and an understanding of complex congenital genitourinary conditions.
- Regular follow-up examinations of renal and urinary function are essential for many patients.
- Sexual function and fertility must be proactively addressed and managed.
- Pregnancy is likely to need preparation (for some) and combined urologic and obstetric care.
- Collaboration with other specialties and urologic subspecialties is essential for safe and appropriate care.

Urologic Considerations in Pediatric Renal Transplantation

Craig A. Peters MD, Armando J. Lorenzo MD, MSc, FRCSC, FAAP, FACS

The child requiring renal replacement most often is a boy with an obstructive uropathy. The challenge for the pediatric urologist is to ensure that the underlying problem that led to damage to the native kidneys will not cause problems to the transplant. These patients require some of the most complex care. It is paramount to develop a therapeutic plan to provide for **several goals: (1) normal urinary drainage from the kidney into a reservoir, (2) a continent reservoir that permits low pressure storage for a socially acceptable time, (3) volitional emptying of the reservoir, (4) absence of infection, and (5) the fewest surgical procedures and patient trauma**. These goals are achievable, but until they are ensured, renal transplantation should be deferred or a plan to achieve these must be in place.

Patient and family understanding and compliance are essential for successful urologic management of the child with an abnormal urinary tract and end-stage renal disease (ESRD). Before the onset of ESRD, a management strategy should be developed to avoid more rapid deterioration of the child's chronic kidney disease and to facilitate a smooth transition into transplantation. The integration of the entire care team in this preparation is critical and demands a close working relationship between the urology team, pediatric nephrology, and the transplant team. The urologist must have a basic understanding of the needs and constraints of the nephrologists and transplant surgeons. The transplant ureteral implantation can be performed by the urologist or the transplant surgeons, but this should depend upon the state of the lower urinary tract and the comfort level of the surgical teams with the particular aspects of the surgery and their postoperative management, including any complications.

Pretransplant Assessment

Screening

A large percentage of children in need of renal replacement have some type of uropathy: congenital obstruction, vesicoureteral reflux, or neuropathic bladder dysfunction (NAPRTCS, 2008; NAPRTCS, 2014; Van Arendonk et al., 2014). Younger boys typically have obstructive uropathy, including posterior urethral valves, whereas the patients with reflux and neuropathic bladder tend to be older, including young adults. Some children have uncharacterized ESRD. It is reasonable to have all children screened for urologic issues before transplant. A detailed history, renal ultrasound, and flow rate with postvoid residual urine by ultrasound (in toilet-trained children) can effectively rule out most significant uropathies. Routine voiding cystourethrogram (VCUG) is not necessary unless there is a history of a specific urologic disease, febrile or recurrent UTI, the presence of hydronephrosis, or abnormal voiding (Ramirez et al., 2001; Singer et al., 2009; Fig. 51.1).

The key element is the history of urologic conditions or symptoms. *CIC,* Clean intermittent catheterization; *PVR,* post void residual; *RUS,* renal ultrasound; *VCUG,* voiding cystourethrogram.

Focused Assessment

The child with a known urologic abnormality requires a targeted pretransplant assessment directed by the underlying condition and the status of the bladder and kidneys. In most, a VCUG is useful to evaluate voiding function, the state of the urethra, and the presence and grade of reflux. When bladder dynamics are abnormal, consideration for urodynamic evaluation is also appropriate. **The indications for urodynamic testing to assess bladder capacity, compliance, contractility and emptying, as well as sphincter function include a known neuropathic bladder abnormality, bladder outlet obstruction resulting from posterior urethral valves (PUV) or a large ureterocele, and selected cases with recalcitrant voiding dysfunction, high-grade hydronephrosis, or recurrent urinary tract infections (UTIs)** (Burns et al., 1992; Riley et al., 2010; Zermann et al., 2003). The principal goals of urodynamic testing are to determine the presence of abnormal bladder dynamics, which may place the allograft at risk and establish the need for further therapy to optimize bladder function. This may include medical therapy with anticholinergics, the use of intermittent catheterization, and the potential need for bladder augmentation.

Urodynamics also provide insight into bladder emptying function, which is critical to minimize the risk of infections. Moreover, if medical therapy for a noncompliant bladder is needed, this may impair bladder emptying and necessitate clean intermittent catheterization (CIC) to permit effective emptying. In the child with a sensate or difficult-to-negotiate urethra, as well as in some patients with neuropathic bladder, the creation of a continent catheterizable stoma may be the ideal way to facilitate effective CIC. It is reasonable to make and execute these decisions before transplant. Urodynamic evaluation often is a regular monitoring evaluation in these children and a critical element in ongoing optimization of bladder function. It often is necessary to repeat the study to ensure that the therapeutic intervention has been effective and that the bladder is indeed ready for the transplant.

Key Points: Urologic Evaluation and Management

- Goals:
    - Normal urinary drainage from the kidney into a reservoir

  - A urinary reservoir that permits low pressure storage for a socially acceptable time
  - Volitional emptying of the reservoir, with continence
  - Absence of infection
  - The fewest surgical procedures and patient trauma
- A large fraction of children in need of renal replacement have some type of uropathy, either congenital obstruction, vesicoureteral reflux, or neuropathic bladder dysfunction.
- Pretransplant assessment is directed by the underlying condition and the status of the bladder and kidneys.
- Urodynamic testing aims to assess bladder capacity, compliance, and emptying, as well as sphincter function.
- Indications for urodynamics include a known neuropathic bladder, history of posterior urethral valves, and children with ongoing voiding dysfunction, high-grade hydronephrosis, or recurrent UTIs.

Pretransplant Preparation

Bladder Preparation

General Issues

The most common early bladder abnormalities associated with ESRD are low capacity, hypercontractility, and poor compliance. Although this is the typical picture in patients with PUVs, it is important to recognize that these bladders continue to evolve over time, progressing to a pattern of resolution of hypercontractility and increasing bladder capacity, up to insufficient contractility and inefficient emptying (so-called "myogenic failure") (De Gennaro et al., 2000; Holmdahl et al., 1996; Nguyen and Peters, 1999; Peters et al., 1990). Of these, hypertonicity and poor compliance are the most dangerous urodynamic patterns, because high pressures will be transmitted to the kidneys even in the absence of reflux. Failure to address these aspects of bladder dysfunction can increase graft loss (Herthelius and Oborn, 2007).

Hypertonicity and Poor Compliance

Initial management is medical, typically with anticholinergics, with augmentation cystoplasty as a second-line intervention (Greer et al., 2016; Lopez Pereira et al., 2000). Medical management requires diligence on the part of the family and follow-up to regularly assesses response to therapy. It usually requires introducing CIC in combination with anticholinergics, although some children with PUVs can learn to void by Valsalva maneuver. In some cases, alpha-blockers may also be employed to further aid with bladder emptying (Abraham et al., 2009; Austin et al., 1999). It should never be assumed that they will be able to do so, thus the need to demonstrate this by repeated low postvoid residual volumes on catheterization or ultrasound.

Because of the side effect profile, anticholinergic therapy is best titrated with increasing doses, watching for changes in catheterized volumes, incontinence, and hydronephrosis. Urodynamic evaluation can more precisely define the efficacy. Often medical therapy is introduced at the same time as CIC, although this is not essential. Compliance with CIC is often an excellent test of future patient/family compliance with the stringent requirements of renal transplant. If a family is unable to manage with CIC, their ability to manage the medical care of a transplant should be questioned. The goal of therapy is for the child to be able to store up to estimated bladder capacity for age, at low pressures (i.e., less than 30 cm H_2O), and gain social continence.

Capacity

Bladder capacity is another element of normal function and is the basis for safe storage and social continence. Bladder capacity can be improved with anticholinergic medication but may ultimately require further interventions such as bladder augmentation. There is a clear shift away from augmentation in all patients, to the extreme that augmentation is not needed in renal transplant (Alfrey et al., 1997; Salvatierra et al., 1999). A cautious, selective approach is warranted because the allograft requires a safe reservoir to avoid damage from high pressures or recurrent infections. Augmentation remains a necessary aspect of urologic management in some children with complex uropathies with ESRD. Current indications include a nonsalvageable bladder (because of exstrophy, tumor, or severe end-stage neuropathic bladder) or failure of medical and CIC therapy to achieve low-pressure storage for up to 3 hours. If pressures are only safe for a shorter period of time or regularly exceed 40 cm H_2O despite maximal medical therapy and catheterization, consideration for augmentation is appropriate.

There is no evidence, nor logic, that bladder augmentation increases the risk of complications during or after transplant, despite some reports (Alfrey et al., 1997). **Conversely, it has permitted many effective transplants into abnormal bladders** (Broniszczak et al., 2010; Djakovic et al., 2009; Koo et al., 1999, Luke et al., 2003; Sheldon et al., 1994; Taghizadeh et al., 2007). There is no single approach or timing that is ideal. Although gastric augmentation gained popularity for ESRD children in the late 1980s and early 1990s—based on the theoretical benefits of secreting acid in a patient who is typically acidotic, limiting infections, and lowering the rate of bladder stones (Traxel et al., 2011)—it currently is rarely offered. Gastric augments have been linked with severe complications (particularly in the pretransplant, anuric group) because of gastric secretion injury to the native bladder segment and the resulting hematuria-dysuria syndrome (Nguyen et al., 1993; Reinberg et al., 1992). Moreover, recent reports of malignancy, particularly in the transplant group, are worrisome (Castellan et al., 2007; Husmann and Rathbun, 2008). Caution and monitoring are essential in patients who have previously undergone reconstruction with gastric segments. Ileum and sigmoid segments are the most commonly employed and remain very useful. Selection depends upon anatomy, prior surgery, and preferences for concurrent continent catheterizable stomas.

The augmented patch rarely creates an issue during the transplant, but the presence and location of the pedicle as well as its anatomic orientation must be recognized by the transplanting team. Similarly, **continent stomas should be placed in such a location to avoid conflicting with the anticipated transplant incision(s) and nearly always must be positioned medial to these.** In most cases, the allograft will be placed in a retroperitoneal location employing a Gibson-type incision (Fig. 51.2). Thus intraperitoneal dissection and location of the stomas do not create major difficulties. However, in infants and small children (<15 kg), the vascular anastomosis may have to be fashioned at the level of the aorta and vena cava, and this may require a transperitoneal approach. In these cases, it would be unusual that an augment or catheterizable channel would be in place; however, anticipation and multidisciplinary planning is key. Coordination between the reconstructive and transplant teams remains essential in all cases.

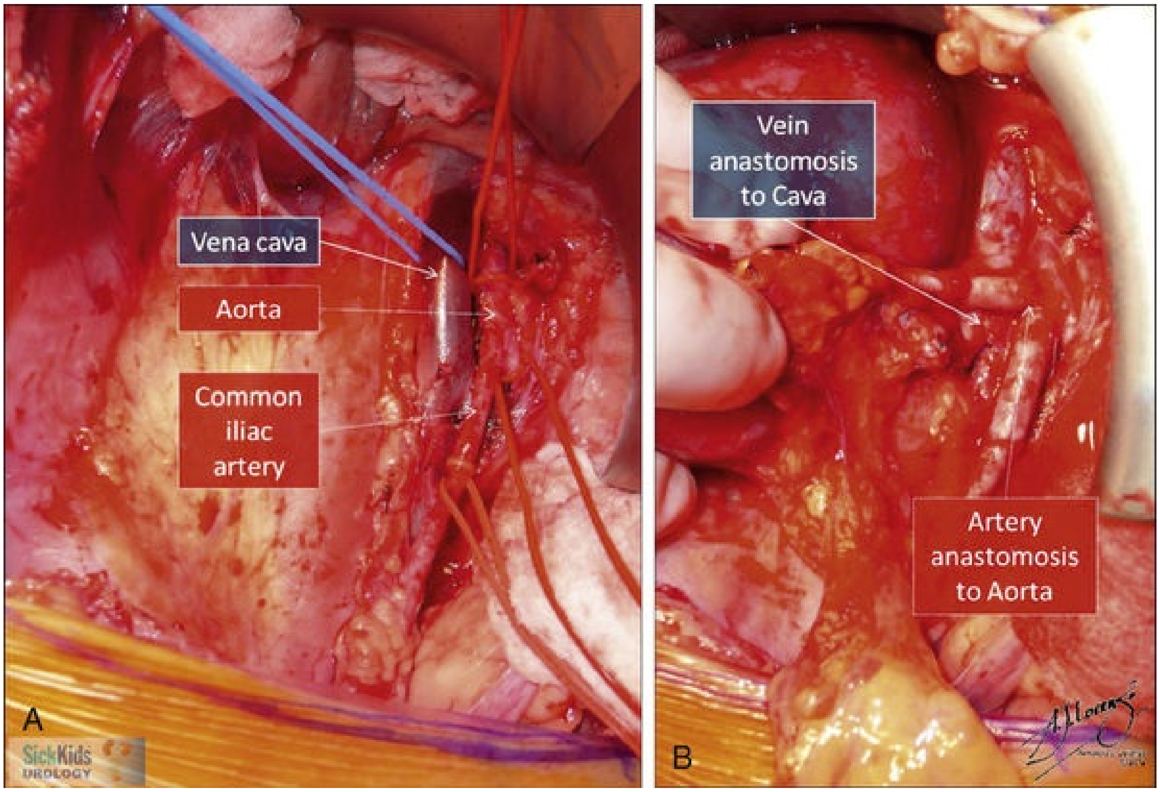

FIG. 51.2 Retroperitoneal dissection through a right Gibson incision in a

small child undergoing a living-related renal transplantation. Adequate space created for an adult-size allograft (A), allowing for a comfortable vascular anastomosis to the aorta and vena cava (B).

Infections

Many children with complex reconstruction of the urinary tract have a history of recurrent UTI, which may be associated with intermittent catheterization and the presence of an augment. This is a potential hazard for the transplant because pyelonephritis of the graft can generate significant morbidity in an immunocompromised host and can ultimately lead to graft loss (Dunn et al., 1987; Hanevold et al., 1987; Howie et al., 2002; Herthelius and Oborn, 2007; Neuhaus et al., 1997). The underlying cause of the infection is most likely urinary stasis resulting from inadequate emptying of the reservoir, either by catheterization or voiding, or urinary obstruction with hydronephrosis (Chu et al., 2013). This must be assessed and addressed in advance of the renal transplant. Strategies include double and triple voiding to avoid using CIC, or—if CIC has already been instituted—to ensure timely and complete emptying. Moreover, it is critical to differentiate true UTIs versus bacterial colonization, which is exceedingly common in patients performing CIC. In general, UTIs do not present a major threat to the renal graft as long as they are managed early and appropriately (Fallahzadeh et al., 2011; Traxel et al., 2011).

Persistent UTIs in the face of appropriate CIC technique suggests either an anatomic abnormality that has not been detected or chronic colonization. The latter sometimes responds to long-term antibiotic courses, using agents including fluoroquinolones or cephalosporins. The cause and specific therapy for this situation is uncertain. Although uncommon, specific anatomic abnormalities such as diverticula or ureteral stumps may require more specific imaging studies and may be amenable to surgical cure.

Clean Intermittent Catheterization

The **use of CIC in managing the abnormal bladder has been a truly revolutionary intervention since its introduction in the 1970s** (Bloom, 2017; Lapides et al., 1972). Although it may be a challenge to initiate, once started it is nearly always well accepted. Careful preparation, teaching, support and follow-up are critically important for long-term success.

The importance and principles of CIC must be well understood by the care providers and carefully communicated to the family, including all possible caregivers. This is a means by which to reduce infection and attain safe bladder storage and control over voiding, which is very important and yet may not be readily apparent on first pass.

The frequency of CIC must be determined by a measure of approximate urine outputs, as well as storage pressures based on urodynamic assessment or by home-catheterization opening pressure measurements (Hidas et al., 2017), and appropriately tailored to fluid intake. This permits an estimate of safe pressure-volume relationships for day-to-day life. Avoiding regular excesses of these volumes and therefore high pressures optimizes healthy kidney drainage. The typical frequency is every 3 and 4 hours. Pressures should not exceed 40 cm H_2O for any prolonged period of time.

Initiating CIC in preparation for transplantation serves an assessment purpose as well. For families for whom follow-through may be imperfect, CIC is a useful means of determining their commitment and ability to follow complex medical care plans. If CIC cannot be instituted pretransplant to manage an abnormal bladder, there is no reason to believe this ability will suddenly manifest post-transplant. **The response to CIC can predict the ability to manage the necessary transplant medication and care regimen as well.** The committed and understanding family will manage well, and this will demonstrate their readiness for transplant.

Defunctionalized Bladder

Neuropathic.

The defunctionalized neurogenic bladder is becoming scarce because of better management but will occasionally be seen clinically in a transplant patient who has not had ongoing urologic care (Firlit, 1976; Serrano et al., 1996). **It is impossible to know without testing what the potential function of the bladder may be. It is also important to recognize that a bladder that has been defunctionalized will take some time to reach its maximal functional potential. This is often best accomplished by bladder cycling to increase capacity, determine bladder wall compliance, and assess the family's ability to perform CIC.**

Some have advocated simply implanting the transplant ureter into the bladder and anticipating normal function (Salvatierra et al., 1999). Although this may occur on rare occasions, it is a highly risky approach to the chronically defunctionalized bladder. A renal allograft should not be employed to test if a bladder functions properly or not; conversely, clearance for transplantation should be granted when bladder function has been adequately assessed and optimized.

Cycling the defunctionalized bladder is best accomplished using a progressive program of catheterization with instillation of increasing volumes of saline, with a set dwell time and then catheter drainage (Alam and Sheldon, 2008). The amounts are determined empirically based on initial tolerated volumes and should increase at regular intervals, usually 10 to 15 cc per day. The response to these instillations gives useful clues regarding the utility of the bladder as a reservoir and any ability to empty spontaneously. Adjunctive anticholinergic medications are often necessary to increase bladder capacity and compliance.

The defunctionalized neurogenic bladder almost certainly requires intermittent catheterization for emptying. It is therefore reasonable to introduce this concept to the family. In the rare instance in which the child can learn to empty satisfactorily, CIC may no longer be needed. This is a major step and requires a careful study of voiding diaries, postvoid residuals, and urodynamic testing.

The target volume is expected capacity for age based on any of the available formulas (Kaeferet al., 1997; Koff, 1983). This may not be reached immediately, but if volumes increase steadily without significant leakage, further expansion is likely. Although storage capacity is important, compliance is equally critical, and this must be formally assessed with urodynamics. Only if acceptable capacity and compliance parameters can be reached should the patient be cleared for transplant. Aggressive medical management is also important in this determination. If adequate storage and compliance cannot be attained, consideration for augmentation must be entertained. This should be performed before transplant unless there are pressing reasons.

Key Points: Pretransplant Preparation

- The most common bladder abnormality associated with uropathy and ESRD is a low-capacity, hypertonic bladder with poor compliance.
- There is no evidence that bladder augmentation increases the risk of transplant.

- Recurrent pyelonephritis is a potential hazard for the transplant and is associated with graft loss.
- Initiating CIC in preparation for transplantation serves an assessment purpose as well as facilitating bladder emptying.
- Bladder re-functionalization is often best accomplished by bladder cycling to increase capacity, determine bladder wall compliance, and assess the family's ability to perform CIC.

Non-Neuropathic.

The defunctionalized bladder associated with renal insufficiency is often due to posterior urethral valves or vesicoureteral reflux. In addition, a small group of anuric patients without prior urologic problems seek transplantation. These include patients who have undergone bilateral nephrectomies, such as patients with severe proteinuria resulting from congenital nephrotic syndrome. These bladders may be more often salvaged to permit spontaneous voiding but should be initially approached as the defunctionalized neuropathic bladder, with the assumption that CIC will be needed long term. The critical factor will be safe storage capacity, and progressive cycling as described earlier can provide that assessment. At the same time, children can be asked to attempt to void after holding the instilled saline for a period of 15 or 20 minutes. A postvoid catheterization then determines the postvoid residual volume.

The ability to empty spontaneously also affects the decision regarding the need for a continent catheterizable stoma. This is more critical in boys with normal sensation who may be understandably resistant to urethral catheterization. The period of pretransplant CIC permits assessment of voiding ability and tolerance of urethral CIC. These decisions are best made concurrently with other reconstructive choices to permit an integrated strategy and a single surgical procedure, if possible.

Decision to Augment.

Although the use of bladder augmentation is declining because of concerns regarding metabolic, infectious, and neoplastic complications, enterocystoplasty remains the most effective means to provide adequate bladder storage function in neurogenic and postobstructive bladder dysfunction (Aki et al., 2006; Barnett et al., 1987; Capizzi et al., 2004; DeFoor et al., 2003; Hatch et al., 2001; Mendizabal et al., 2005; Nahas et al., 2002;

Rigamonti et al., 2005; Sheldon et al., 1994; Traxel et al., 2011). To lose a renal graft because of the same processes that contributed to native renal demise is unacceptable. The potential complications of augmentation must also be clearly recognized and anticipated, although some reports (Alfrey et al., 1997) have presented extreme examples that are not our personal experience. A strategy of aggressive intermittent catheterization with medical management becomes the best approach to identify those patients in whom augmentation is the only real option for successful renal transplantation. It is difficult to determine a meaningful incidence of the need for augmentation as the effort expended by family and health care team varies as much as the underlying pathology. With early aggressive bladder management, the need for augmentation in neuropathic and obstructive bladder dysfunction has been declining.

Broad indications for augmentation before transplantation would be the inability to develop capacity greater than 75% of expected for age with pressures below 30 cm H_2O, using catheterization that is no more frequent than every 3 hours, and using maximal anticholinergic medications. Although there has been an increase in use of botulinum toxin injection in patients with neuropathic bladder dysfunction (Greer et al., 2016), the safety and efficacy after transplantation is largely unknown. Irrespective of the anticholinergic agent, tolerance to medication obviously is an important factor. Admittedly, these thresholds remain somewhat arbitrary and lack strong clinical data to support them. It is also critical to remember the dynamic nature of bladder dysfunction, as previously described for patients with PUVs. In addition, the development of long-term complications in a time-dependent fashion (Metcalfe et al., 2006) as well as the potential added complications of performing an augmentation cystoplasty in a post-transplant (immunocompromised) setting should be taken into account. It is not an easy decision and should clearly be individualized. For example, because many patients with PUVs eventually develop myogenic failure, it seems prudent to postpone as much as possible augmentation cystoplasty in this population (Jesus, 2015), providing this delay does not accelerate progression to end stage.

The availability of a dilated ureter to permit ureterocystoplasty (Kim et al., 1996; Kurzrock et al., 2002; Landau et al., 1997) should be explored, although results have been mixed and dependent on ureteral diameter, bladder compliance, and presence of vesicoureteral reflux. It is preferable to enterocystoplasty in terms of certain issues such as mucous production, stone formation, recurrent infections, or metabolic abnormalities. In this context, efforts should be made to preserve the ureter when possible for this use, for fashioning a continent catheterizable channel, or to use as a target for allograft ureteral anastomosis (Penna et al., 2017).

Cutaneous Stomas

The defunctionalized bladder may be associated with a variety of urinary diversions, including ileal and colon conduits as well as pyelostomies or ureterostomies. In the past, transplantation has been performed with the ureters draining into the diversion (Kelly et al., 1966). This is rarely accepted today, although it remains an option in very selected cases and at the expense of higher complications, particularly UTIs (Broniszczak et al., 2010; Jesus, 2015). A functioning ileal loop diversion in the setting where augmentation is determined to be necessary can be used as the augmenting patch with bladder refunctionalization, even if the patient is anuric. If augmentation is not needed (based on response to CIC cycling) and the patient continues to produce urine, the native kidney should be implanted to refunctionalize the bladder and the loop discarded. If there is uncertainty regarding the need for augmentation, the loop may be preserved and kept available for later augmentation (including after transplant).

Reconstruction Strategies

In the setting in which bladder reconstruction will be needed, several factors must be considered in anticipation of the renal transplant. These considerations include the type of dialysis (either hemo- or peritoneal), likely placement of the graft, timing relative to initiation of dialysis (if not already begun) and transplantation, the need for bowel surgery, and the status of the native kidneys.

Dialysis Issues

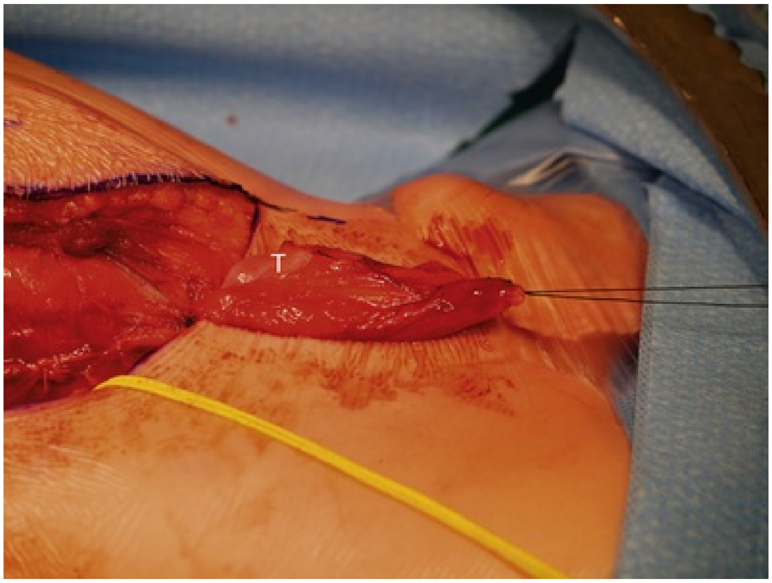
If a patient is already on peritoneal dialysis (PD), any intraperitoneal surgery will likely require temporary or permanent transition to hemodialysis. Limiting this to one procedure is valuable. At times an intraperitoneal procedure can be performed at the time of PD catheter placement, but if bowel surgery is required, doing so may increase the risk of catheter infection and need for removal.

If the patient is not yet on dialysis but is approaching the need for renal replacement therapy, there may be some consideration for initiating dialysis before reconstruction to improve the metabolic status of the child. This can promote wound healing, decrease complications, and help the child tolerate the metabolic demands imposed by reabsorption of urine in cases in which bowel will be employed. At the same time, extensive intra-abdominal surgery may preclude the use of the peritoneum for dialysis. Last, for those on hemodialysis, there is a risk of catheter infection in the setting of postoperative sepsis and arteriovenous fistula injury during surgery because of low-flow states or direct pressure.

Graft Placement

Consideration should be made for the most likely future location of the graft. In the very small child, in whom the graft may be placed intraperitoneally, careful movement of any mesenteric pedicles away from the midline is advisable, as well as trying to avoid a transureteroureterostomy. Thankfully, very small children are unlikely to have prior reconstructive procedures, and most allografts can be accommodated using an extraperitoneal approach (Chinnakotla et al., 2017; Gander et al., 2017; Vitola et al., 2013). A prior psoas hitch or extensive dissection for ureteral reimplantation of the native kidney (if it is to be salvaged) can make ipsilateral iliac graft placement difficult.

The need for additional (nonurologic) procedures and challenging vascular anatomy should also be taken into consideration. In patients with primary hyperoxaluria, a concurrent or prior liver transplant places space and dissection restrictions on the right upper quadrant and flank. This makes any future surgical procedures to address problems with the right native kidney very difficult and favors placement of the renal allograft on the left side. Thrombosis of the vena cava or iliac system dictates the best location for the venous anastomosis, and avoidance of this area (as well as respecting any collateral venous drainage) will be of value. Last, the presence of an uncorrected ipsilateral undescended testicle should be addressed (eFig. 51.3). The resulting peri-allograft inflammatory reaction and fibrosis make any subsequent attempts at finding or mobilizing the testicle extremely difficult.



EFIG. 51.3 Dissection of intra-abdominal testicle *(T),* with orchidopexy at time of transplantation in a young child with renal failure on peritoneal dialysis. Because of possibility of hemodialysis and limited vascular access orchidopexy was previously deferred.

The urologist may have few feasible alternatives in difficult cases, and in such situations, careful documentation of the procedure and collaboration with the transplant team is essential. As with many other reconstructive procedures, a detailed operative report and a diagram of the operation are bound to be of great value to future surgeons (eFig. 51.4).

Timing

In general, it is preferable to perform any major urologic reconstruction before transplantation (Taghizadeh et al., 2007). Minor ureteral surgery may be considered at the time of transplantation, but this is unusual. After enterocystoplasty or continent diversion, at least 6 to 12 weeks are recommended for adequate healing. Unilateral native nephrectomy is reasonable at the time of transplantation. Concurrent procedures should be avoided in infants and small children because they may experience more negative outcomes with a prolonged anesthetic and hemodynamic instability. Moreover, these patients often require anticoagulants to prevent graft thrombosis (Dick et al., 2005), thus increasing the risk of postoperative bleeding.

Enterocystoplasty

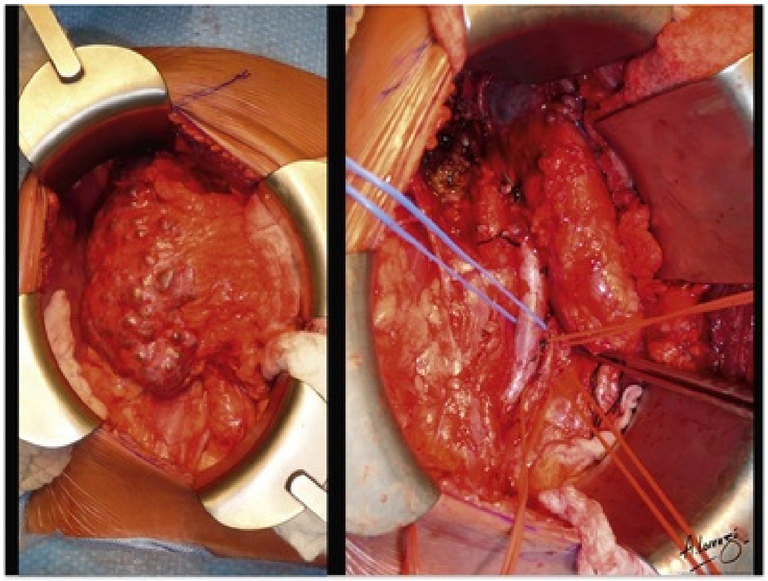
Enterocystoplasty in the setting of a dialysis patient or a child approaching ESRD is feasible and, when needed, can be successfully accomplished in a manner similar to any other child (DeFoor et al., 2003; Sheldon et al., 1994;

Taghizadeh et al., 2007). The selection of bowel segment(s) and reconstructive strategy should be based on the functional anatomy and needs of the individual child. These include factors such as the need for a continent catheterizable stoma, the availability of native bladder tissue, the status of the bladder neck and continence mechanism, and bowel function. **If continent diversion is needed because of an unsalvageable bladder, there is no reason to defer this until after transplant.** The often-quoted metabolic problems with continent diversion in the setting of renal impairment are not an absolute contraindication. These patients need careful medical management after diversion, and in cases in which pre-emptive transplantation is considered, dialysis may be needed. In some cases, by improving bladder dynamics and limiting infection, the progression to ESRD may be delayed.

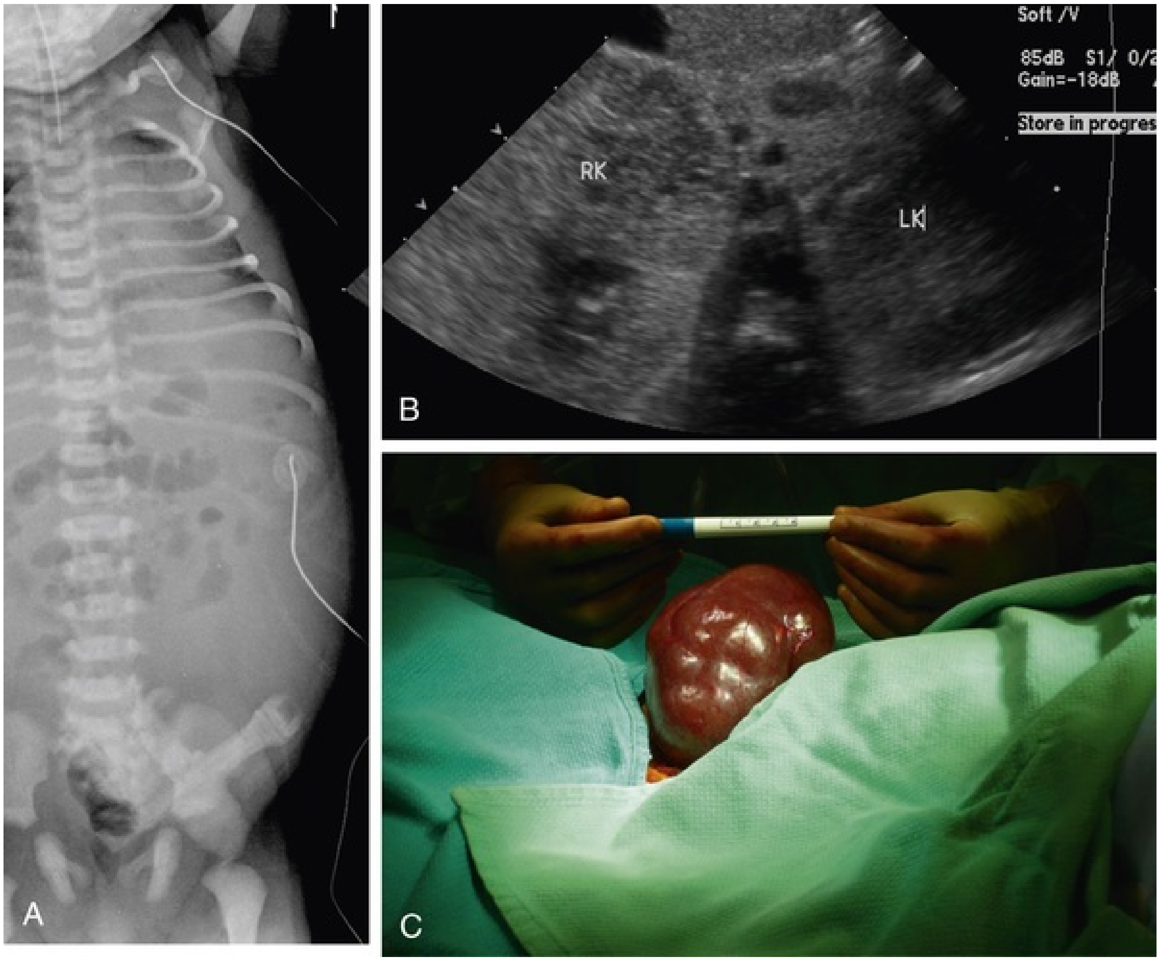
The use of gastric segments was considered particularly appropriate for the child approaching end-stage failure and in very selected cases may still be useful (Burns et al., 1992; DeFoor et al., 2003; Traxel et al., 2011). Because of the various complications of gastrocystoplasty, however, this approach has lost popularity. The benefit of acid excretion for the child with CKD is undeniable, but these children are still at risk for complex metabolic derangements including alkalosis. For the anuric child, the presence of gastric secretions can lead to bladder erosion and even perforation (Reinberg et al., 1992). In addition, development of dysuria and hematuria can be particularly challenging (Castellan et al., 2012). Care must be taken in those children to use proton pump inhibitors and to irrigate with bicarbonate solutions until urine output is restored.

Native Nephrectomy

The decision regarding native nephrectomy must be made as a multidisciplinary team. There is controversy in this regard and, although in general it is preferable to leave the native kidneys (Fraser et al., 2013), **there are several situations in which removal pretransplant is necessary. These include difficult-to-control hypertension, profound nephrotic syndrome with malnutrition resulting from protein losses (Kim et al., 1992), massive polyuria (Kravarusic et al., 2006), recurrent upper tract infections, large stone burden, high risk for malignancy, very large kidneys (to gain space for the allograft** [eFig. 51.5]**) or allow for dialysis** [eFig. 51.6]**), and massive vesicoureteral reflux.** The latter may be relative, but with stasis and possible infection in an immunosuppressed child, removal may be preferable and less risky than reimplantation or conservative management. The utility of leaving a native kidney that produces some urine is in making dialysis more manageable with lower fluid restrictions, which can facilitate nutritional support in the younger child. This must be balanced against the possible risks of infection and hypertension, as well as graft function.

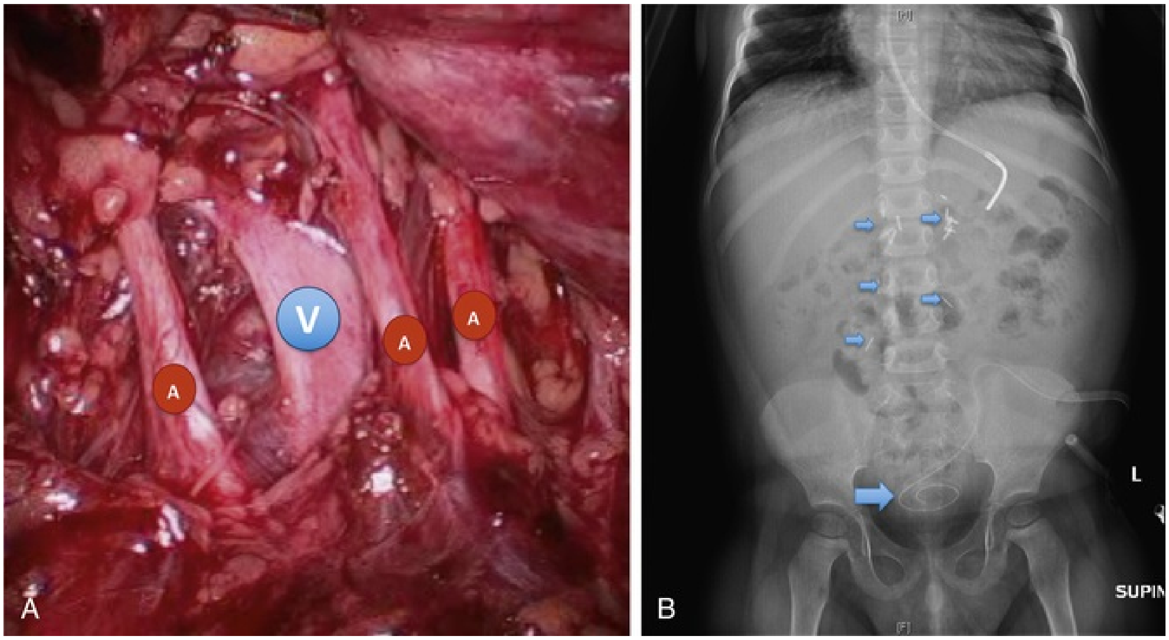


EFIG. 51.5 Native nephrectomy at the time of renal transplantation in a child with autosomal kidney disease. Note amount of spaced gained by the procedure, along with easy access to vena cava, aorta, and iliac system.

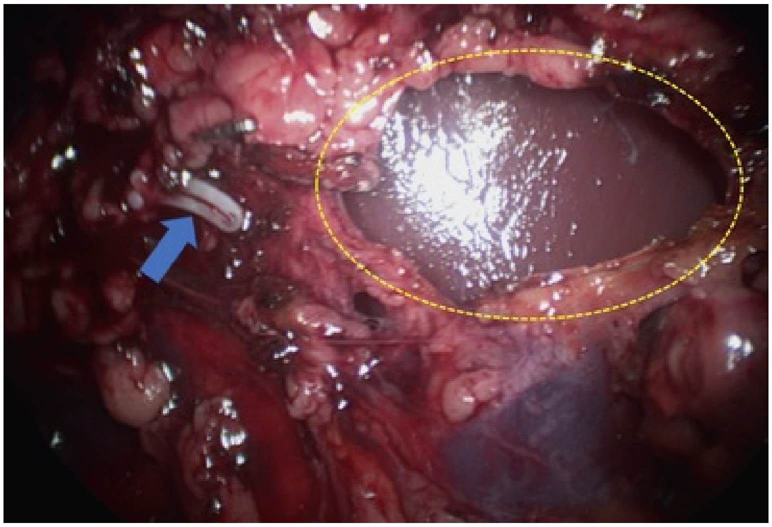


EFIG. 51.6 (A) Abdominal radiograph of a neonate with autosomal recessive polycystic kidney disease (note gas distribution and displacement of diaphragm). (B) Ultrasound showing right and left kidney (*RK* and *LK*), touching in the midline. (C) Intraoperative picture at time of nephrectomy. Note the large size of native kidney.

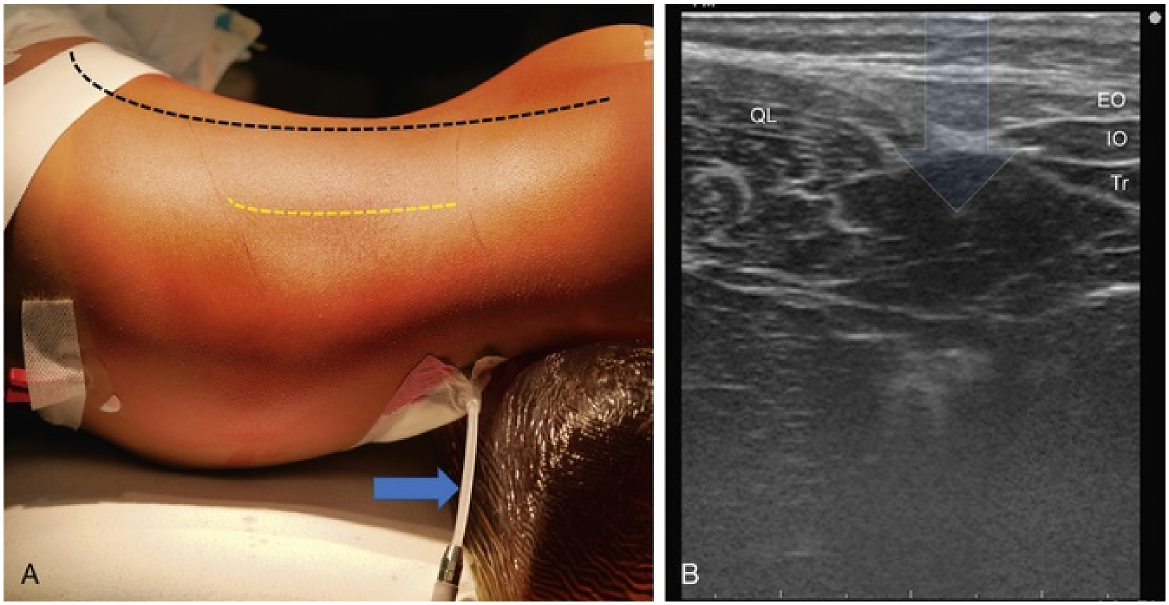
In a child in whom native nephrectomy is to be performed, the main factor to choose the best approach is whether the patient is on peritoneal dialysis (PD). If so, entering the peritoneal cavity (either open or laparoscopically) requires temporary hemodialysis. Moreover, open surgical procedures may trigger adhesions and scarring of the peritoneal membrane, thus making subsequent PD ineffective. Some advocate for attempts at immediate or early PD after transperitoneal surgery, but the risk of leakage and possible infection would argue against this practice. Conversely, retroperitoneal nephrectomy can be performed with immediate PD (eFig. 51.7; Gundeti et al., 2007), but leaks may still be encountered if the peritoneum is disrupted (eFig. 51.8). When bilateral nephrectomies are performed on the same setting, the prone approach offers some advantages, such as the ability to perform both procedures without repositioning (eFig. 51.9). If the kidneys are relatively small, this is the optimal approach. For children on PD with large kidneys, a posterior open nephrectomy or laparoscopic nephrectomy with morcellation are suitable options.



EFIG. 51.7 Exposure of renal hilum during laparoscopic retroperitoneal nephrectomy in a child on peritoneal dialysis. (A) Note the accurate identification of renal vein *(V)* and multiple renal arteries *(A).* (B) On postoperative abdominal radiograph, metal clips can be seen on the area of hilar dissection *(small arrows),* and the functioning peritoneal dialysis catheter tip coiled in the expected position *(large arrow).*



EFIG. 51.8 Peritoneal disruption during dissection of hilum during laparoscopic retroperitoneal dissection. Note clip securing the hilum *(arrow).*



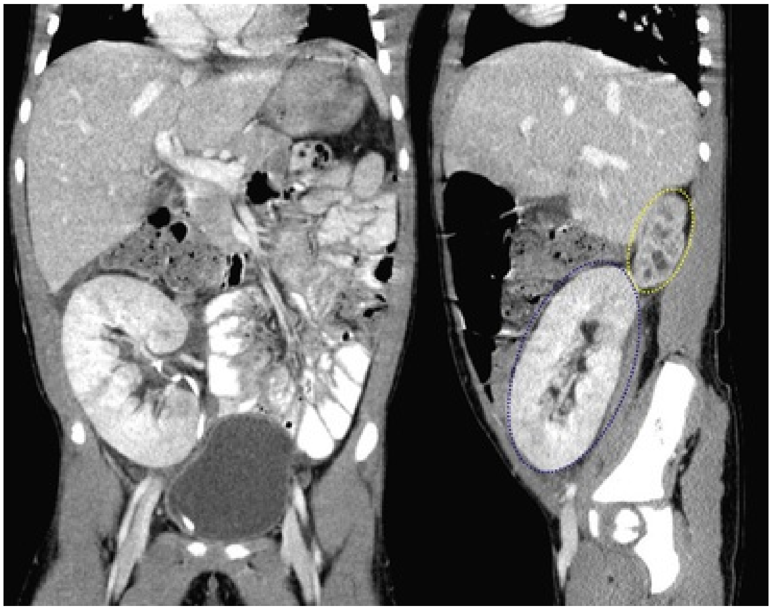
EFIG. 51.9 (A) Positioning for prone laparoscopic retroperitoneal nephrectomy. Note the placement of bolsters under the chest and pelvis creating gentle curvature *(black line)* to gain space when developing retroperitoneal space. Also, peritoneal dialysis catheter *(arrow)* is placed to gravity to check for intraperitoneal gas leaks or bleeding. The entry point can be estimated based on anatomic landmarks *(yellow line).* (B) Alternatively, intraoperative ultrasound may help define the most optimal point for entry, medial to the abdominal wall muscles (external oblique *[EO],* internal oblique *[IO],* and transversus *[Tr]*), and lateral to quadratus lumborum *(QL).*

If PD is not being performed, then any type of nephrectomy is acceptable. With laparoscopy the incidence of postoperative adhesions is limited and is unlikely to affect the future efficacy of PD. The ureter should be preserved and transected as high as possible. There is the potential impact on the ultimate transplant procedure when the distal ureter is removed, thus causing adhesions in the area of the iliac vessels. Furthermore, the native ureter may be used as a target for allograft anastomosis (Penna et al., 2017). However, if there is significant reflux or obstruction and a dilated ureter, total removal may be best to limit the risk of infection. In selected cases with high risk for complications with open or laparoscopic nephrectomy, renal embolization may be attempted as a reasonable alternative (Capozza et al., 2007).

Managing Patients With Native Kidneys

Avoiding Removal

In the absence of specific indications for nephrectomy, leaving the native kidneys in place offers the advantage of having a potential source of water excretion if the graft fails. In addition, there may be benefit in preserving the native kidneys for erythropoietin production and vitamin D metabolism, as well as avoiding the potential complications of a nephrectomy. Although this can be helpful in managing nutrition and lifestyle, it should not become a rigid goal if there are reasons to remove the kidneys. Their ultimate utility may be very limited, particularly after a period of graft function, because they often regress in size and urine output. Most allograft can be easily transplanted without removing the native kidneys, particularly if these are small or atrophic (eFig. 51.10).



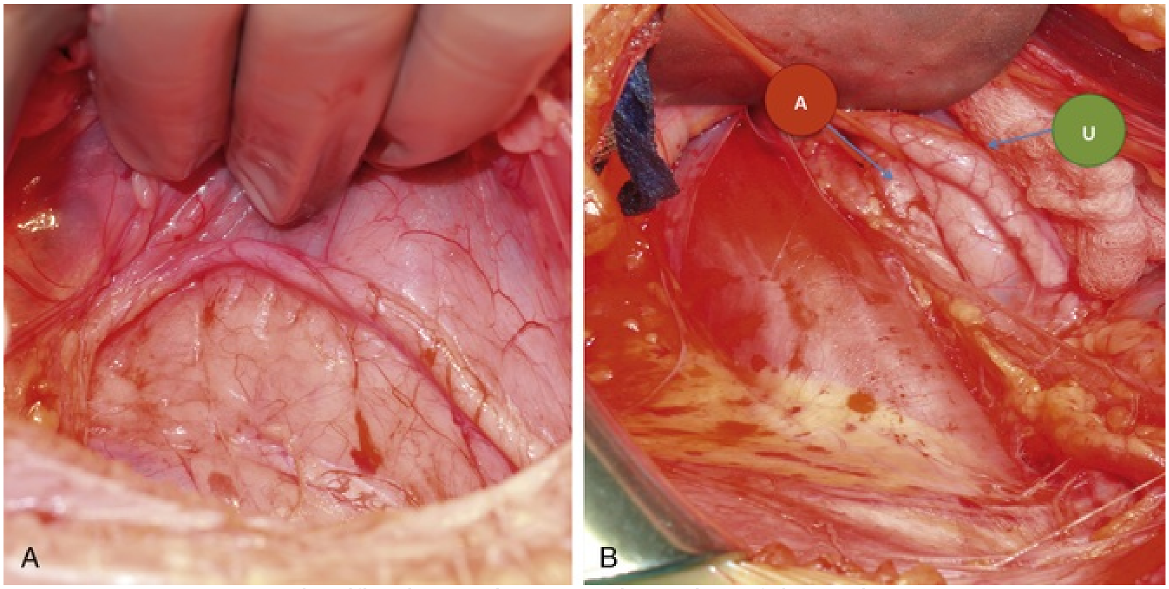
EFIG. 51.10 CT scan of patient with renal transplant on right side and native kidneys in place. Allograft encircled in blue, native kidney encircled in yellow.

Limit Risk of Infection

Urinary infection in the setting of an immunosuppressed host with a renal transplant is damaging to the child and the graft. Preventing infection in patients with known urologic issues is therefore a priority that should be acted upon proactively, rather than purely in response to an infection. The additive damage and morbidity may be critical in the long-term outcome of that child. Situations in which active prevention of infection may be useful include high-grade reflux, persisting hydronephrosis (Chu et al., 2013) with or without reflux, and children who depend on intermittent catheterization. These patients are frequently colonized with bacteria and may be more susceptible to UTI. The nondilated, nonrefluxing native kidney is unlikely to be subject to infection and can generally be maintained in the absence of other indications for removal. It is reasonable to discuss with families the protective value of circumcision in boys at risk for ESRD and consider the procedure early on (before transplantation) (Mukherjee et al., 2009; Singh-Grewal et al., 2005).

Ureteral Preservation

When nephrectomy is to be performed, ureteral preservation should be considered. If the ureter is normal, it should always be left to limit surgical dissection near the iliac vessels and to have an option for primary or salvage uretero-ureterostomy for distal ureteral stenosis (eFig. 51.11; Kockelbergh et al., 1993; Lapointe et al., 2001; Penna et al., 2017). If bladder function is abnormal and intermittent catheterization may be needed, preserving the ureter for use as a continent stoma is also advisable. This is best performed pretransplant; however, creation of the continent stoma at the time of transplant remains an option.



EFIG. 51.11 Identification and expected location of the native ureter during exposure for retroperitoneal placement of renal allograft. The native ureter is often encountered during medial dissection of the peritoneum (A); and the ureter *(U)* can be seen crossing on over the iliac vessels *(A)* when dissection proceeds toward the pelvis (B). This is a common location for performing a uretero-ureterostomy.

Combining Nephrectomy and Transplant

Native kidneys may be removed at the time of the renal transplantation, but this is generally avoided to limit surgical morbidity and time under anesthesia. It may be appropriate for a single ipsilateral native kidney, which may be swiftly removed through the transplant incision. In the absence of specific justification, however, this strategy is best avoided.

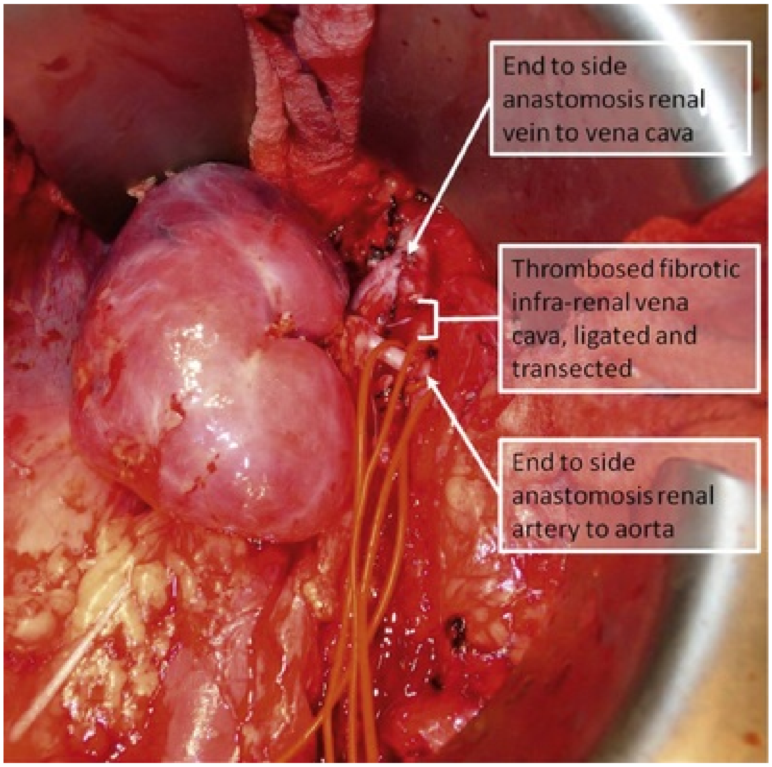
Key Points: Pretransplant Reconstruction

- The ability to empty spontaneously will also affect the decision regarding the need for a continent catheterizable stoma.
- Indications for augmentation before transplantation include the following:
  - Capacity less than 75% of expected for age
  - Pressures above 30 cm H_2O
  - Catheterization every 3 hours
  - Maximal anticholinergic medications
- For patients on peritoneal dialysis, intraperitoneal surgery will likely require temporary transition to hemodialysis.
- In general, any major urologic reconstruction should be undertaken well before anticipated transplantation.
- Native nephrectomy is indicated for:
  - Malignant hypertension
  - Profound nephrotic syndrome with malnutrition resulting from protein loss
  - High risk for malignancy
  - Recurrent upper tract infections
  - Massive reflux

Transplantation

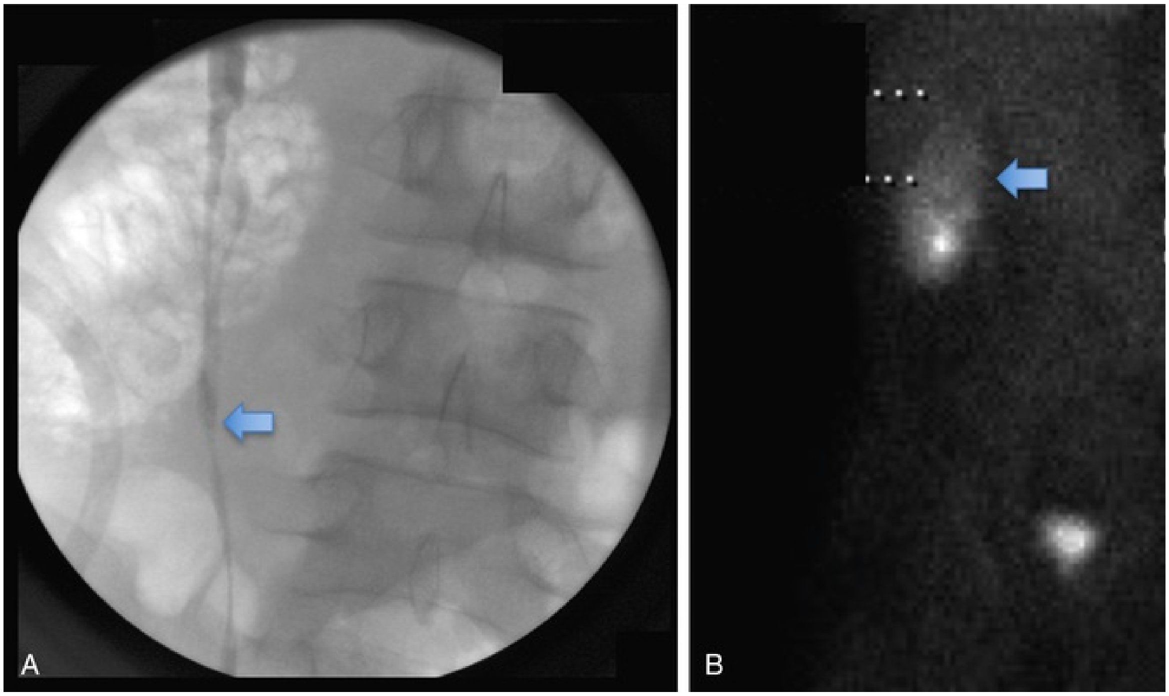
The technical elements of the vascular component of renal transplantation are described in Chapter 88, and the principles remain appropriate to children.

Although pediatric urologists have different levels of involvement in this aspect of care, it is important to understand some situations that may have implications with urologic management. These include the implications of transplantation of infants or patients with prothrombotic states, which usually demands the use of anticoagulation. This has important implications in terms of bleeding risk and need for careful hemostasis during bladder surgery. Also, vascular targets are critical, and location may be driven by availability of adequate sites for arterial and venous anastomosis rather than convenience for urinary tract reconstruction (eFig. 51.12). The urologist must adapt and be able to address limits imposed by the length of the donor kidney, which may have to be addressed with creative use of the native ureter or bladder flaps. Examples include transplantation in an orthotopic location (eFig. 51.13) or an "upside down" allograft resulting from a more favorable position of the artery and vein (eFig. 51.14). Meticulous vascular dissection is imperative to avoid vessel damage, vasospasm (eFig. 51.15), or subsequent thrombosis, as well as careful ligation of lymphatics to prevent lymphoceles (eFig. 51.16). In addition, particular attention should be paid in cases with multiple renal arteries. Damage to an arterial branch creates a permanent area of ischemia (with subsequent scar and loss of parenchyma). Lack of perfusion to the lower pole heralds the additional risk of ureteral ischemia (eFig. 51.17). Thus great efforts should be expended to vascular reconstruction of lower pole vessels, even if small in caliber (eFig. 51.18).

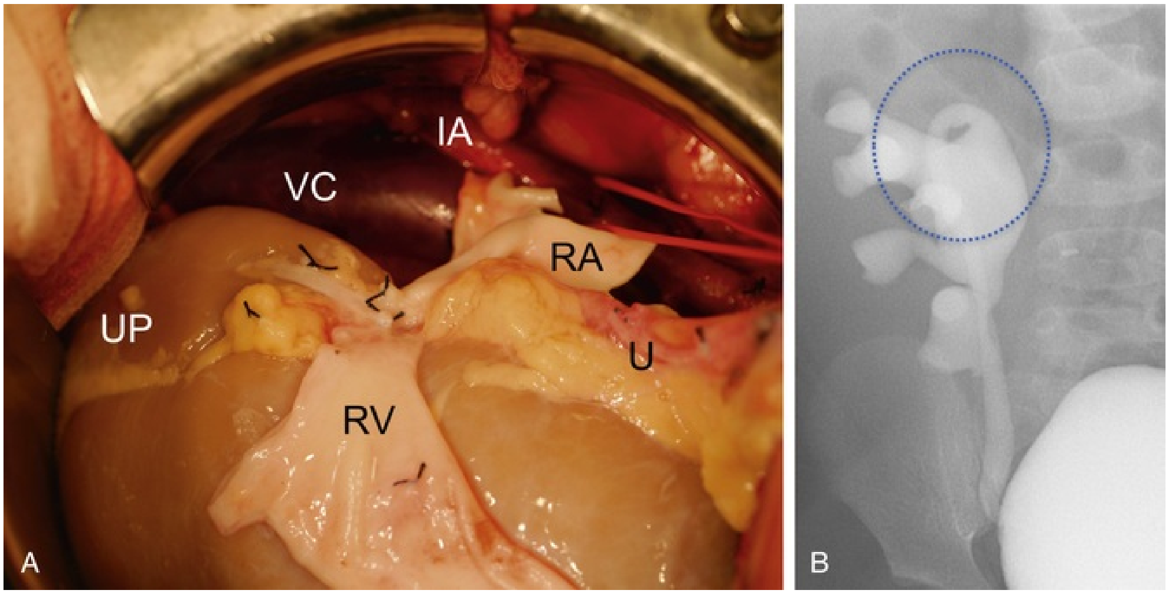


End to side anastomosis renal vein to vena cava
Thrombosed fibrotic infra-renal vena cava, ligated and transected
End to side anastomosis renal artery to aorta

EFIG. 51.12 Renal transplantation with venous anastomosis between donor and recipient renal vein to address prior infrarenal vein thrombosis. Note placement of allograft in an anatomic location, which demands appropriate strategies to reconstruct the lower urinary tract (i.e., reimplantation of a long donor ureter, ureteroureterostomy, or reimplantation on a bladder wall flap).

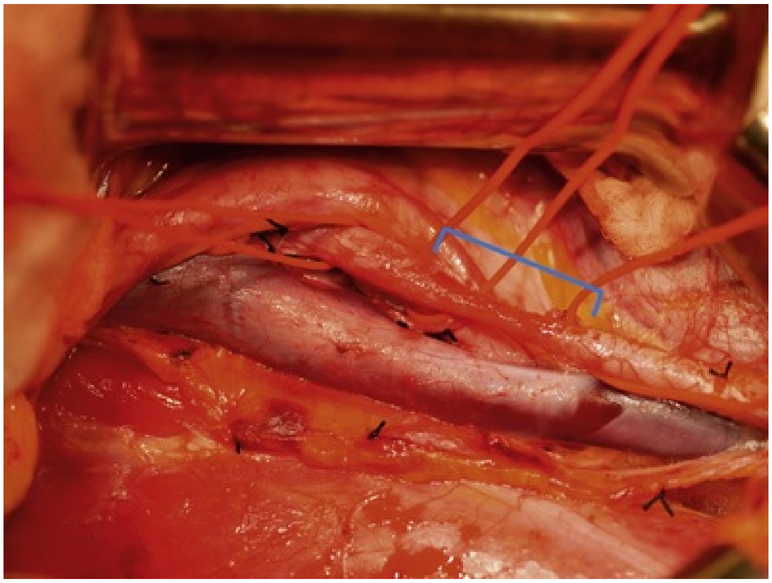


EFIG. 51.13 Orthotopic renal transplantation in a child with abnormal infrarenal vasculature. (A) Note use of the native ureter for reconstruction (retrograde pyelogram at time of stent removal), with end-to-side uretero-ureterostomy between the donor ureter and the proximal native ureter, near the renal pelvis. (B) Drainage confirmed on postoperative renal scan.

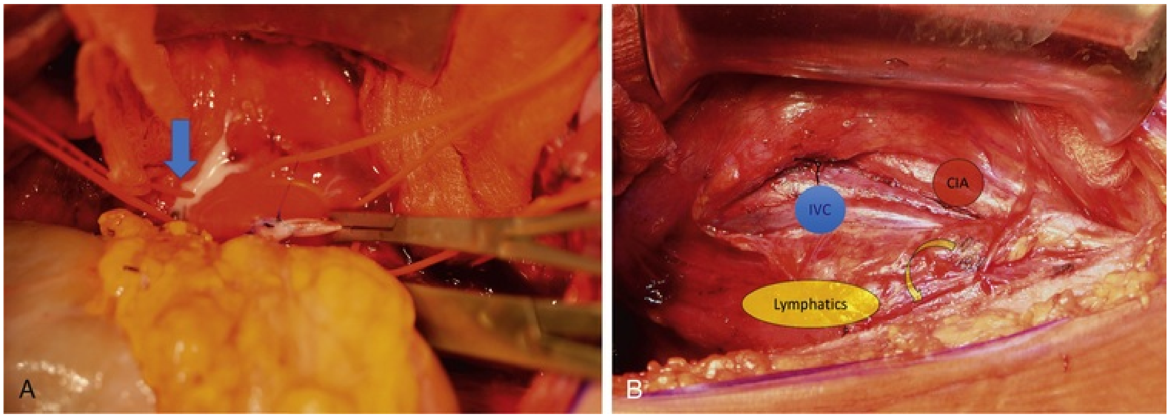


EFIG. 51.14 Retroperitoneal placement of right allograft in right flank and fossa. (A) Allograft in orthotopic orientation, with cephalad location of the upper pole *(UP)* and expected position of the donor ureter *(U).* The

anatomic configuration of the renal artery *(RA)* and renal vein *(RV)* precludes anastomosis to the vena cava *(VC)* and iliac artery *(IA)* without twisting or crisscrossing the vessels. By repositioning the allograft in an “upside-down” fashion, the anastomosis is successfully performed. (B) Postoperative voiding cystourethrogram showing reflux with the location of the ureteropelvic junction towards the upper pole. The kidney showed minimal hydronephrosis and adequate draining on postvoid images.

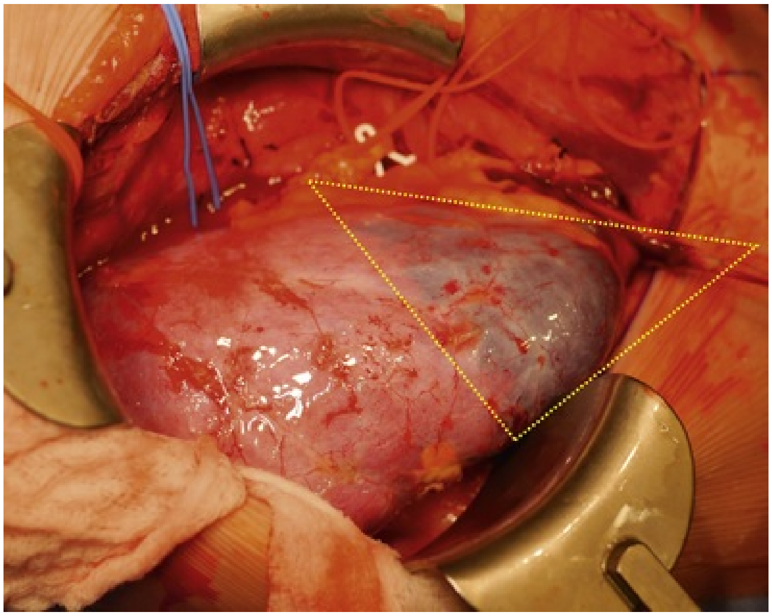


EFIG. 51.15 Spasm of the external iliac artery during mobilization *(bracket).* Without correction, anastomosis at this site may lead to poor perfusion and thrombosis of the allograft and/or lower extremity ischemia.

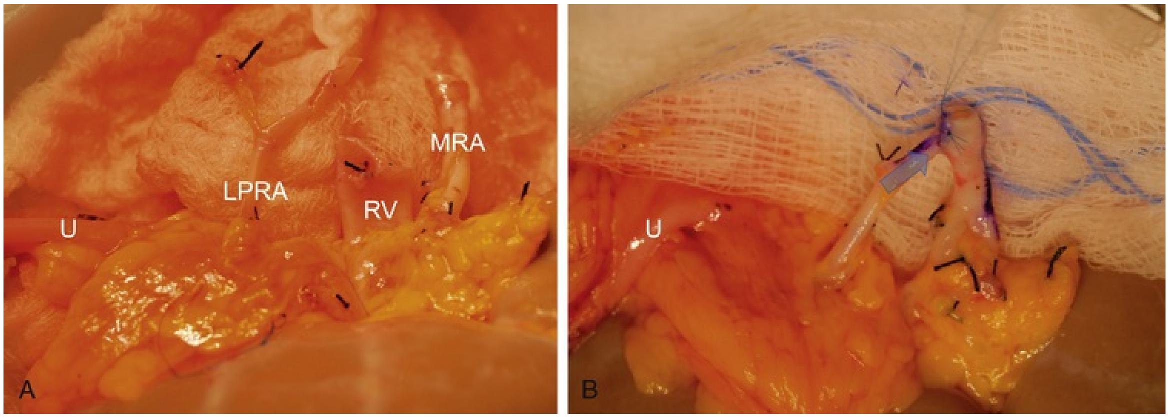


EFIG. 51.16 (A) Intra-operative evidence of lymphatic leak *(arrow)* noted during vascular anastomosis. (B) Careful dissection and ligation of lymphatics is critical to minimize this situation and avoid postoperative

lymphoceles. When prominent lymphatic channels and nodes are encountered, these may be reflected and tacked to the psoas muscle rather than dividing *(curved arrow).*



EFIG. 51.17 Lower pole ischemia after allograft reperfusion, likely resulting from damage to lower pole branch. This, along with extensive dissection in the area of the “golden triangle” (confined by ureter, kidney, and renal artery), increases the risk of ischemic ureteral complications, such as urine leak and strictures.



EFIG. 51.18 (A) Bench dissection of living-related renal allograft, with known lower pole renal artery *(LPRA)* noted during exposure of the main renal artery *(MRA),* renal vein *(RV)* and ureter *(U).* (B) Lower pole artery anastomosed to main renal artery *(arrow)* before transfer to surgical field

for revascularization.

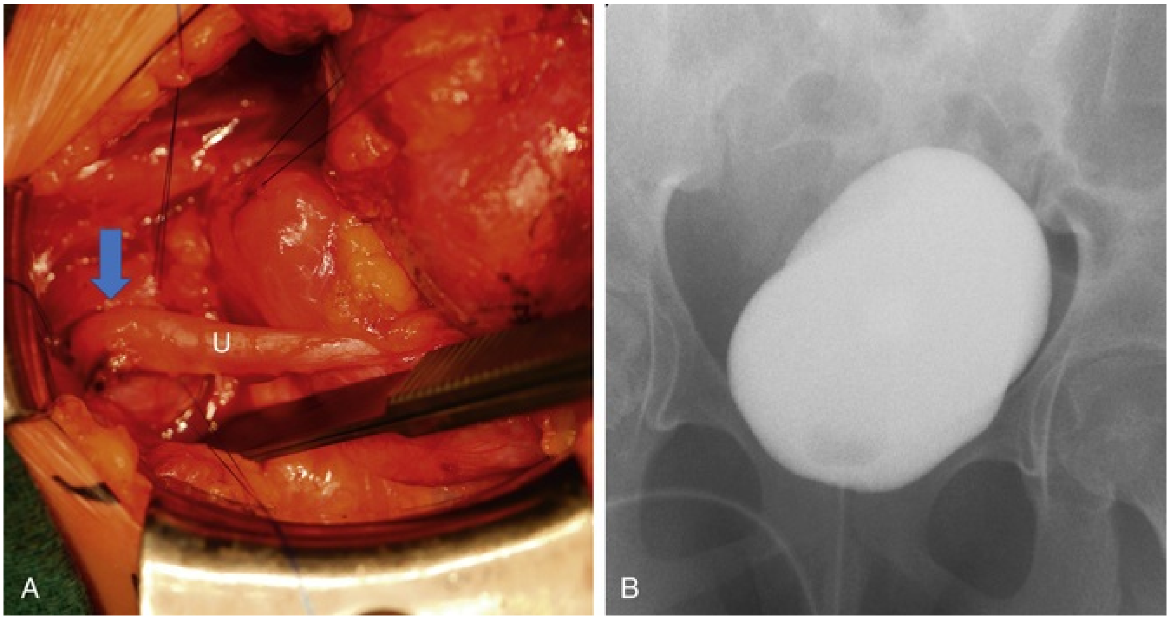
For the pediatric urologist who is not involved in performing the vascular anastomosis, the lower urinary tract reconstruction becomes the focus of intraoperative attention, as well as of urologic complications.

Ureteral Anastomosis

Surgical Techniques and Options

As with ureteroneocystostomy for VUR, there are intravesical and extravesical techniques for the transplant ureteral anastomosis. We favor a nonrefluxing anastomosis in most cases in which reimplantation into the bladder is planned, although clearly this is not always essential. Careful screening can identify patients with bladder dysfunction and therefore at risk for graft reflux; however, this method to prevent reflux is simple, effective, and with minimal morbidity.

Extravesical ureteroneocystostomy is the preferred ureteral bladder anastomosis. After graft perfusion and hemostasis, the bladder is partially filled with saline or a dilute antibiotic solution. The anterolateral aspect is cleared and traction sutures are placed to mobilize the lateral aspect upward and to provide tension on the vesical wall. The ureter is sized to ensure it will reach. The detrusor is incised to the level of the mucosa for a length of about 3 to 3.5 cm in an anatomic direction, avoiding kinks in the donor ureter. Flaps of detrusor are elevated away from the mucosa, and a small disc of mucosa is excised at the distal aspect of the trough. The bladder drains, and the traction sutures keep the trough in position. The ureter is trimmed loosely to length and spatulated for 4 to 5 mm. An interrupted mucosa-to-mucosa anastomosis is performed using a fine absorbable suture. A monofilament is preferred. The detrusor flaps are then brought over the ureter. No advancement stitch is used, but two stitches are placed through the detrusor and the adventitia of the terminal ureter to prevent eversion. The detrusor is closed with interrupted absorbable sutures, mindful of not tightening too much the entry point of the ureter (eFig. 51.19). Alternatively, the widely known Barry technique (Barry, 1983; Barry and Hatch, 1985) may be used, whereby a 4-cm tunnel is created between parallel incisions through which the ureter is passed. A shorter tunnel has been used in some pediatric centers with acceptable outcomes (Vasdev et al., 2011).



EFIG. 51.19 (A) Donor ureter nonrefluxing reimplantation, with anastomosis to bladder and approximation of detrusor flaps over the ureter *(arrow).* (B) Postoperative cystogram demonstrating absence of vesicoureteral reflux.

If the bladder wall is particularly abnormal and thick, a longer tunnel is developed and the flaps are dissected back a bit further to provide a more robust antireflux tunnel and limit the risk of obstruction, because these are typically abnormally functioning bladders. Implanting the graft ureter into an augmented bladder poses additional challenges and it is preferred to perform the ureteroneocystostomy into the detrusor. On occasion this demands an intravesical approach through the augment to reach the detrusor, which may be impossible to mobilize effectively otherwise. If there is no detrusor available, anastomosis into the bowel segment is reasonable and technically easier than into a colonic or gastric segment. It is advisable to perform a nonrefluxing ureteroneocystostomy in these settings because these patients are inevitably on intermittent catheterization and often colonized with bacteria.

Transplant to the native ureter (uretero-ureterostomy) is routinely performed in some centers with good results (Gurkan et al., 2006; Lapointe et al., 2001; Penna et al., 2017). The procedure can be performed in an end-to-side or end-to-end fashion, based on surgeon preference and the presence of a native kidney. When the native kidney is in place, some advocate ligation of the proximal ureteral segment without major complications and a low rate of subsequent nephrectomies (Timsit, et al., 2010; Torino et al., 2016). It remains unclear if this option is superior to ureteroneocystostomy but is appealing in cases with a normal, nonrefluxing native ureter, a small bladder, or a short donor ureter or when pelvic dissection is difficult because of previous surgery. Moreover, this option is available as a salvage procedure in the setting of post-transplant ureteral stenosis.

Ureteral Stenting

The role of routine ureteral stenting in pediatric transplant is highly debated, with lack of conclusive data to demonstrate its routine utility (Dharnidharka et al., 2008; French et al., 2001; Simpson et al., 2006). There are situations in which ureteral stenting is appropriate, including a difficult implant (particularly in an abnormal bladder) or when the graft ureter appears traumatized or devascularized. In adult series, stenting has been shown to be an advantage for cadaveric donors in terms of reducing the incidence of ureteral complications from 5.8% to 1.9% but at a higher risk of infection (Fayek et al., 2012). If a stent is to be used, a short double-J ureteral stent is placed and generally removed in 4 to 6 weeks, although some advocate early removal (5 days post-transplant) by securing the stent to the tip of the urethral catheter or employing an externalized stent or splint (Ter Haar et al., 2017). This strategy may decrease stent-related complication and infections (Patel et al., 2017). Removal of an internal stent requires cystoscopy and can be coordinated with other procedures, such as removal of a tunneled intravenous access or renal biopsy.

Key Points: Transplant Ureteroneocystostomy

- Extravesical ureteroneocystostomy is the preferred ureteral anastomosis.
- Transplant to native uretero-ureterostomy is an effective option.
- There are no data to support routine ureteral stenting at the time of transplantation.

Complications

The urologic complications of pediatric renal transplantation are discussed in this section. Those related to the graft directly, including vascular and rejection issues, are dealt with in Chapter 88. Table 51.1 presents a summary of selected recent reports of urologic complications in pediatric renal transplantation. The unique analysis of Khositseth et al., comparing the incidence of urologic complications in transplant recipients having a history of obstructive uropathy or reflux to those without that history, shows the increased risk of all urologic complications in patients with pre-existing uropathy (Khositseth et al., 2007). Posterior urethral valves have been associated with an increased risk of graft dysfunction in some series (Adams et al., 2004; Luke et al., 2003), yet not in others (Fine et al., 2011; Kamal et al., 2011; Nuininga et al., 2001). In nearly all series, however, obstructive uropathy is associated with a higher risk of urologic complications. Special vigilance and a lower threshold for intervention are appropriate in this population.

Urine Leaks

Urine leaks are typically identified in the early postoperative period with increasing fluid from the wound drains or a perinephric collection on ultrasound. The fluid's creatinine level can determine if this is a urine leak as opposed to lymph or peritoneal fluid (if a transperitoneal approach was employed or there a peritoneal opening occurred during the procedure). At first presentation, it is critical to assess all urinary drainage tubes, particularly the indwelling bladder catheter. If the catheter is in place, it is reasonable to irrigate it and check for patency. If it has been removed, it is often best to replace it. A transplant ultrasound is performed to determine if there is hydronephrosis, although its absence does not rule out obstruction. If hydronephrosis is present, distal ureteral obstruction should be suspected and consideration for a percutaneous nephrostomy should be entertained. If a stent was employed, adequate position should be documented. The level of the leak must then be determined, and either a MAG3 scan (assuming adequate graft function) or a cystogram may be useful. The latter can identify a bladder leak at the site of the anastomosis or a leak within the pyelocaliceal system if a stent is in place and reflux of contrast is achieved (Fig. 51.20). Although a CT scan can be effective, exposure to intravenous contrast may adversely affect renal recovery.

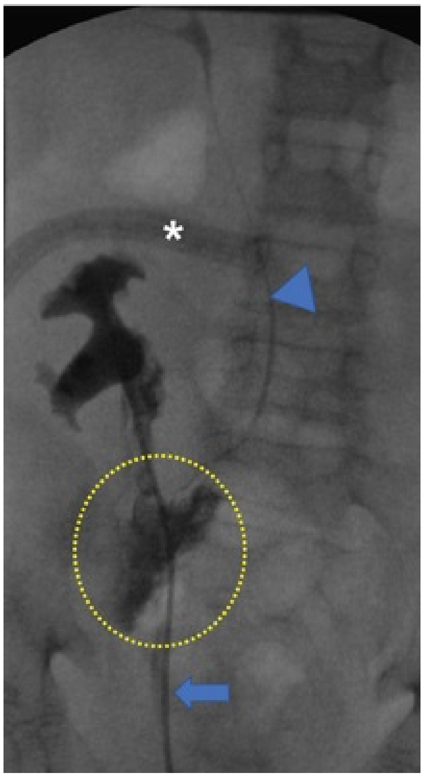

FIG. 51.20 Detection of leak at site of uretero-ureterostomy during cystogram with retrograde flow of contrast around a stent *(arrow).* Note reflux into native ureter *(arrowhead)* up to renal pelvis as well as presence of a drain (*). Leak initially detected by increase in drain output with fluid having a high creatinine concentration.

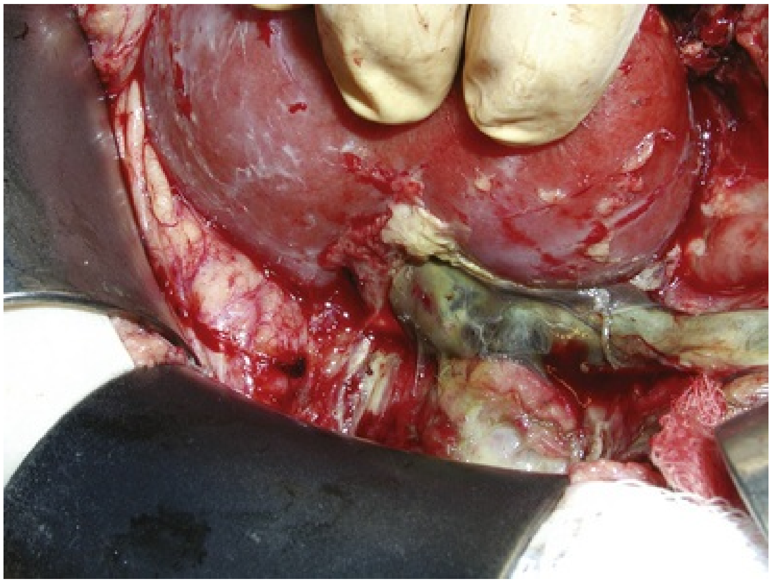
The indications for intervention are clinically based, and if the leak is limited, an observational approach is reasonable. We have seen leaks in the setting of very high post-transplant urine output in smaller children simply because of a small bladder catheter. If a larger catheter may be placed, this may facilitate resolution. If there is persistent worsening or a large urine leak despite adequate bladder drainage, percutaneous renal drainage and/or exploration may be needed.

The goal of exploration is to identify the cause, confirm the location of the leak, and provide for repair. If the leak is bladder based, revision of the anastomosis with closure of the defect and adequate drainage is effective. However, if the leak is due to distal ureteral necrosis, some means of ureteral replacement is needed. For a short segment of necrosis, bladder mobilization and reimplantation is effective. If a long segment of ureter has been lost, native ureter, either ipsilateral or even contralateral, may be useful (if available). A psoas hitch or bladder flap may be needed if the native ureter is not present.

These strategies are similar to those used for ureteral strictures. Careful stenting and drainage are essential (eFig. 51.21).



EFIG. 51.21 Ischemic loss of the entire renal pelvis and ureter in a cadaveric renal graft into a patient with a gastrocystoplasty. This presented with urine leak after a period of ATN. The graft was salvaged with an augment-bladder flap to the lower calyces of the graft.

Infection

Urinary infection is a long-term and often delayed complication that largely reflects the status of bladder function and underlying urologic causes of renal failure (Herthelius and Oborn 2007; Silva et al., 2010). The presence of hydronephrosis is often associated with pyelonephritis and worsening renal function (Chu et al., 2013). Routine assessment of bladder emptying, determining the presence of hydronephrosis, and selective use of a voiding cystourethrogram usually identify the underlying cause. If the patient is on CIC and no specific correctable cause is present, a strategy of prevention by way of prophylactic antibiotics and bladder irrigation may be effective. Aggressive management of bladder dysfunction, which should have been identified pretransplant, is essential to preserve graft function. If VUR is present into the graft and febrile infections with altered renal function are documented, surgical correction is warranted. Reflux in the absence of infection and with normal bladder function may be observed.

Reflux

Vesicoureteral reflux into the transplant kidney is entirely distinct from routine reflux into an otherwise normal renal unit based upon the fact that this is a reimplanted ureter, that the risk to renal function of an episode of pyelonephritis is greater in a transplanted kidney, and that the patient is immunosuppressed (Coulthard and Keir, 2006; DeFoor et al., 2003). Routine evaluation for reflux after renal transplant has been performed in some centers, even though not all cases require surgery. Identification of this potential risk factor is useful for clinical decision making and ongoing risk assessment. If febrile UTIs occur, a cystogram is clearly indicated as the presence of transplant reflux justifies surgical correction with an open ureteral reimplantation (Hanevold et al., 1987; Krishnan et al., 2006). The risk of subsequent episodes of allograft pyelonephritis is significant (Barrero et al., 2007; Neuhaus et al., 1997; Ranchin et al., 2000) and increases the potential for graft loss (Herthelius and Oborn, 2007; Fig. 51.22). Identification of simultaneous bladder dysfunction is equally important (Casale et al., 2005), although this may not always be correctable. In the setting of intermittent catheterization, a lower threshold for reflux correction should be exercised because these bladders will be chronically colonized. Reflux in the absence of infection and bladder dysfunction may be observed and attempts made to improve bladder and bowel function. There are no data to suggest that low-grade sterile VUR into a renal graft is harmful in children. Close observation for possible infection or deteriorating bladder function is warranted.

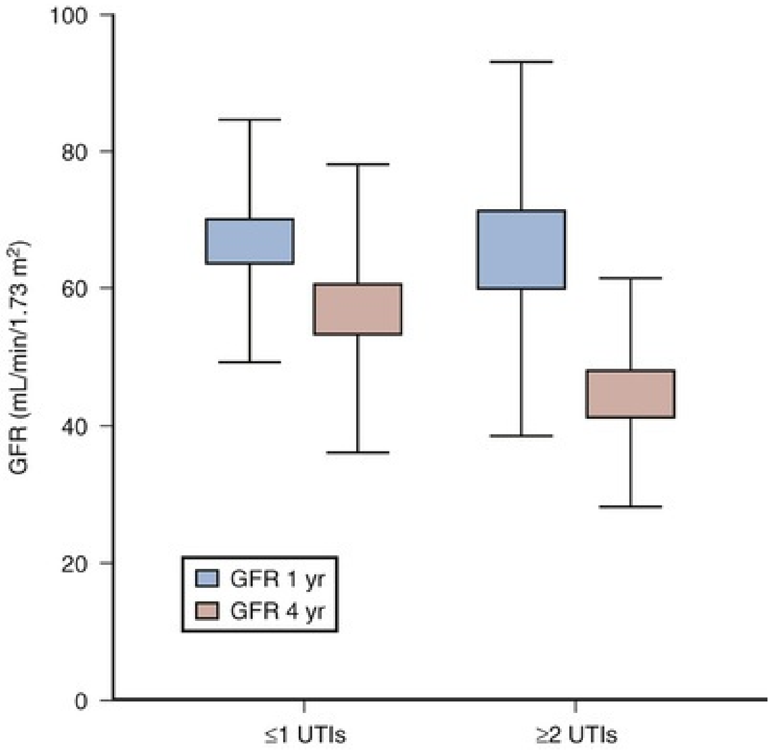


FIG. 51.22 Graft function at 1 and 4 years in children with ≤1 and ≥2 urinary tract infection. (From Herthelius M, Oborn H: Urinary tract infections and bladder dysfunction after renal transplantation in children. *J Urol* 177:1883–1886, 2007.)

Surgical management of reflux into a transplanted ureter is never routine. The role of endoscopic therapy is limited, and the few reports available suggest limited benefit, with resolution rates of 50% to 80% (Kitchens et al., 2006; Vemulakonda et al., 2010; Williams et al., 2008). This may be an option for asymptomatic reflux, but in the face of an episode of febrile UTI, a more definitive intervention is justified. There are few data regarding relative efficacy of intravesical compared with extravesical methods (Krishnan et al., 2006), but the authors' preference is intravesical, often using extravesical mobilization. A transtrigonal technique is effective if the contralateral native ureter can be avoided. Otherwise an advancement or Politano-Leadbetter technique may be used. Ureteral stenting is advisable.

If the transplant ureter was anastomosed to the ipsilateral native ureter, options are similar, yet the response to endoscopic injection and difficulty with dissection may be different and more favorable because of the preservation of the patient's ureterovesical junction.

Hydronephrosis and Obstruction

A frequent urologic complication in pediatric renal transplant is development of hydronephrosis, and intervention for ureteral obstruction may be needed in as many as 8% of transplants (Chu et al., 2013; Shokeir et al., 2005; Smith et al., 2010). The presence of hydronephrosis necessitates careful evaluation and selective management to tailor appropriate treatment to the individual. The transplant kidney appears to be particularly sensitive to obstruction, and the degree of impairment does not always correlate with the grade of hydronephrosis. In most cases, obstruction is heralded by increasing renal dysfunction with a rising creatinine. Hydronephrosis is identified on ultrasound or delayed drainage on MAG3 renal scan. **More than half of obstructions in a recent series occurred within the first 100 days post-transplant** (Smith et al., 2010). In the setting of normal prior bladder function, this pattern indicates ureteral obstruction until proven otherwise. If bladder dysfunction is known (or suspected) to be present, then both factors must be evaluated and managed, as obstruction is more frequent in patients with bladder abnormalities, particularly PUVs (Smith et al., 2010; Fig. 51.23). Placement of an indwelling catheter may be a reasonable first step because improvement in hydronephrosis and renal function may point toward a problem with bladder function.

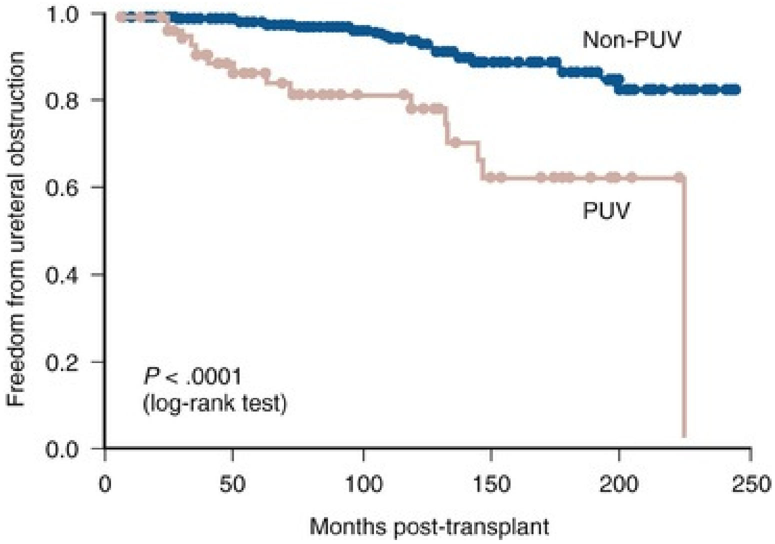

FIG. 51.23 Obstruction-free survival in pediatric renal transplant patients with and without a history of posterior urethral valves. (From Smith et al.: Risk factors and treatment success for ureteral obstruction after pediatric renal transplantation. *J Urol* 183:317–322, 2010.)

In the setting of a rising creatinine and hydronephrosis, obstruction and rejection may be intermingled. If the hydronephrosis is mild and there are other signs of rejection, the most efficient first step is biopsy (Khater and Khauli, 2012). If there is no clinical suggestion of rejection and dilation does not improve with bladder drainage, ureteral stenting (with or without a biopsy) is a reasonable next step. Although vesicoureteral reflux is unlikely to cause progressive hydronephrosis and worsening renal function, it is reasonable to verify that reflux is not present. Diagnostic studies for obstruction in the transplant setting are not completely reliable, and given the associated risks it is warranted to have a low threshold for stenting to assess the impact on renal function. It has been in this setting, albeit rarely, that an acutely failing transplant will show subsequent improvement in function, even in the absence of rejection. The more common situation is with moderate hydronephrosis and a rising creatinine with some rejection on biopsy. If the graft is not failing rapidly, initial medical treatment of the rejection is justified, with stenting being reserved for lack of improvement. If negotiating a stent in a retrograde fashion is not successful, percutaneous drainage is justified. Subsequent antegrade studies will show the location of the obstruction, and a stent can be advanced in the same setting.

The cause of ureteral obstruction is usually in the distal ureter with stenosis at the reimplantation site (Martino et al., 2013), but may be anywhere along the ureter and include an element of ischemia (particularly toward the distal aspect of the donor ureter). In a recent analysis, neither ureteral implant method nor use of stents was a contributing factor to obstruction. Bladder abnormalities, particularly because of posterior urethral valves, however, represent a risk factor of post-transplant obstruction (Smith et al., 2010). Extrinsic compression from a lymphocele (Fig. 51.24) or mass effect from post-transplant lymphoproliferative disease (PTLD; Fig. 51.25) are also possible causes (Buell et al., 2006; Dharnidharka et al., 2001).

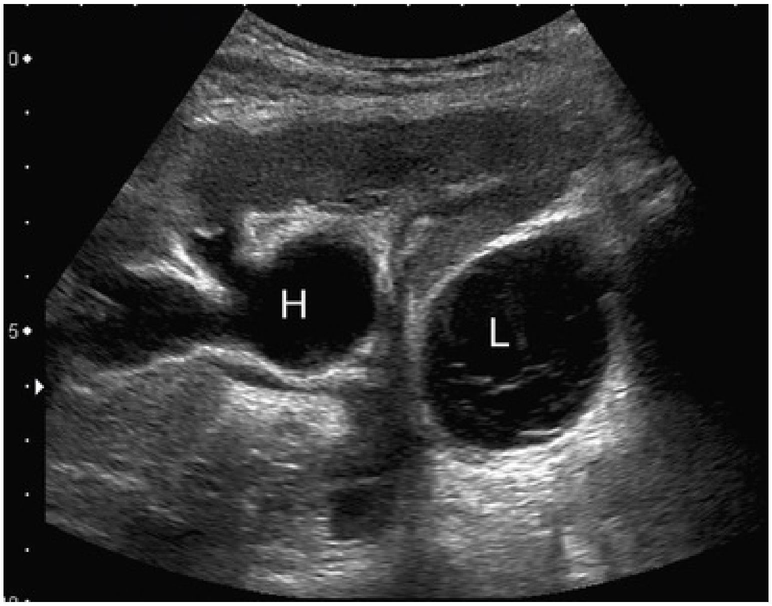

FIG. 51.24 Ultrasound image of renal allograft demonstrating hydronephrosis *(H)* secondary to extrinsic compression resulting from a septated fluid collection (lymphocele; *L*).

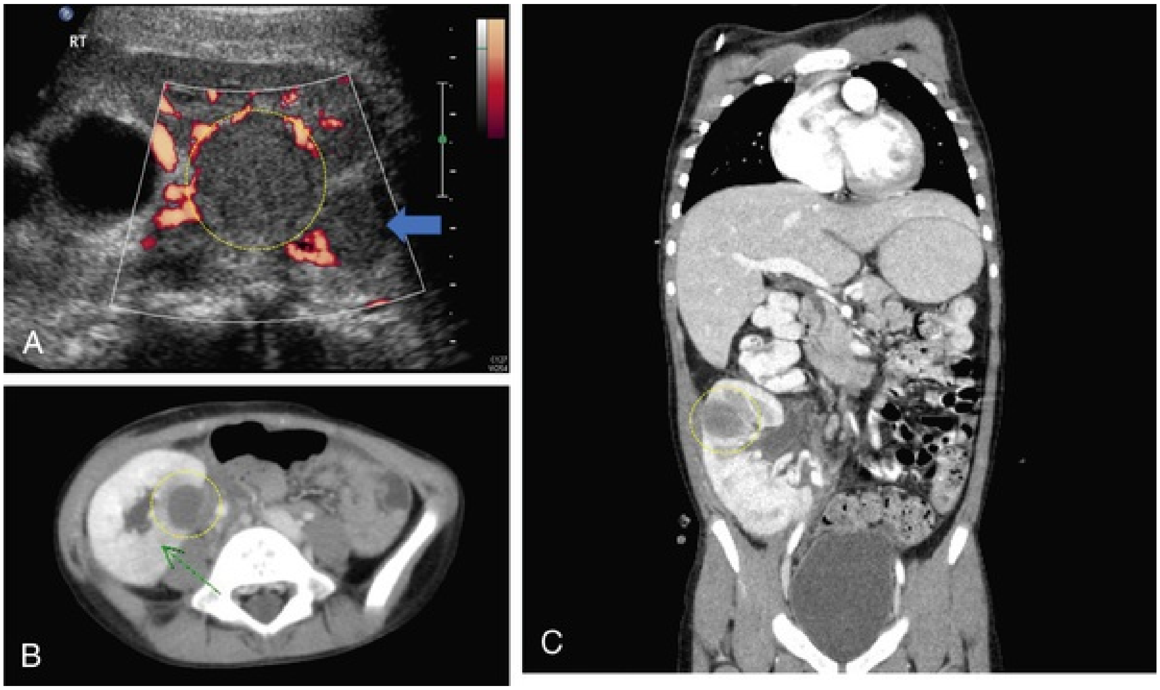

FIG. 51.25 Imaging studies with examples of post-transplant lymphoproliferative disease (PTLD). (A) Intrarenal mass with associated lymphadenopathy *(arrow)*. (B and C) CT scan images depicting PTLD lesions. An allograft mass after transplant should be considered PTLD until proven otherwise.

Definitive therapy is determined by the most likely cause. Focal ureteral narrowing on retrograde imaging may be effectively treated with balloon dilation and stenting for 4 to 6 weeks. Long-term stenting has been used in adult series with thermolabile nitinol stents, but it is uncertain if this would be a satisfactory approach in children (Bach et al., 2013). Recognizing the risk posed to the graft resulting from obstruction, open definitive repair should not be delayed excessively (Smith et al., 2010). As previously mentioned, these procedures entail complex reconstruction using native ureter or bladder flaps (Kockelbergh et al., 1993). Avoiding use of nonurothelial segments, such as appendix (Corbetta et al., 2012), is advisable, although any of these methods may be needed. Pyeloureteral anastomosis can be an option if the native ureter remains in place and is healthy (Sandhu et al., 2012). All of the principles of reoperative reconstruction must be followed to preserve well-vascularized functional tissues.

Bladder Dysfunction

Bladder dysfunction may increase the risk of infections but may also create an obstructive process that impairs renal graft function (Herthelius and Oborn, 2006; Herthelius and Oborn, 2007, Nahas et al., 2008; Van der Weide et al., 2006). Discriminating this from ureteral obstruction may not be simple and, on occasion, has necessitated sequential diagnostic drainage steps. If a bladder catheter can be placed easily, then continuous drainage for 1 to 2 weeks with reassessment of creatinine can usually identify bladder dysfunction as the cause of graft dysfunction if the creatinine declines. If not, then combined stent and bladder drainage followed by a re-check of the creatinine is needed. Elements of bladder and ureteral dysfunction may contribute to graft failure. Both may have to be addressed. Treating bladder dysfunction involves measures to increase compliance using anticholinergics as well as instituting or enhancing an intermittent catheterization program. Bladder augmentation may also be needed, although only after aggressive medical management has been tried. When intermittent catheterization per urethra is difficult, creation of a continent stoma may be needed. As discussed in the beginning of the chapter, identification of these potential risks to graft function is best accomplished before the transplant whenever possible.

Stones

Nephrolithiasis in a pediatric renal transplant is uncommon, occurring in up to 5% of patients (Khositseth et al., 2004), but more likely to be less than 1% (Stravodimos et al., 2012), yet potentially dangerous for long-term graft survival. With appropriate management, stones were not seen to increase the risk of graft loss but were associated with more UTIs (Khositseth et al., 2004). Previous reports have suggested a high incidence of bladder stones, yet many of these were due to retained suture material in the bladder (Lipke et al., 2004). Detection of an asymptomatic stone on routine surveillance should prompt attempts at removal as well as a search for an underlying predisposing factor. Stones associated with renal graft dysfunction resulting from obstruction or infection should be managed with urgent intervention to ensure drainage and prompt removal. All conventional means of stone management are appropriate in a renal graft but should be modulated by recognition of the potential balance of risk to the graft as well as relative efficacy of the various modalities. Selection of modality that will have the highest likelihood of success with a single intervention is likely to be the best option in the long term, even if this incurs more complexity. A lower pole stone may be best managed with a percutaneous approach or ureteroscopic removal rather than extracorporeal shock wave lithotripsy, given the lower success of clearance of lower pole stones. These decisions should be individualized based upon clinical presentation, location and size of the stone, and renal functional status.

Key Points: Complications

- Common urologic complications for pediatric renal transplant include ureteral stenosis (6%), urinary leaks (3%), stones (2%), and clinically significant reflux (2%).
- Urine leaks are typically identified in the early postoperative period with increasing fluid from the wound drains.
- Urinary infection is a long-term and often delayed complication that largely reflects the status of bladder function.
- Vesicoureteral reflux into the transplant is entirely distinct from routine reflux as the risk to renal function of acute pyelonephritis is greater.
- In the setting of a rising creatinine and hydronephrosis, obstruction and rejection may be both present.

- The cause of ureteral obstruction is usually in the distal ureter with stenosis at the reimplantation site.
- Bladder dysfunction may produce infection but may also create an obstructive process that impairs renal graft function.
- Nephrolithiasis is uncommon but may occur in up to 5% of patients.

Summary

Preparation and management of the pediatric transplant patient, particularly with an underlying urologic condition, requires a thorough understanding of the patterns of bladder dysfunction and clear strategies for evaluation and treatment before transplant. Anticipating the needs and constraints of the transplant procedure and being involved in all cases permits a smoother procedure and ongoing continuity of care by the pediatric urologist. Post-transplant monitoring should be diligent to identify pathological processes before they have damaged renal graft function irreversibly. This takes a high index of suspicion and a clear sense of which patients are at high risk for these outcomes. A multidisciplinary collaboration between pediatric nephrology, urology, and the transplant surgical team is critical to maximize patient and graft survival.

Pediatric Genitourinary Trauma

Bruce J. Schlomer MD, Micah A. Jacobs MD, MPH

Renal Injuries

Epidemiology

Renal injuries are the most common form of pediatric genitourinary trauma. The pediatric kidney is thought to be more susceptible to trauma when compared with the adult kidney for several reasons. The pediatric kidney is protected by less perirenal fat and less developed abdominal wall muscles. The pediatric kidney also sits lower so is less protected by the rib cage. In addition, the pediatric vertebral column may be more pliable, leading to more stretch injuries on the ureters. However, it is unclear whether children are more susceptible to genitourinary trauma when compared with adults (Brown et al., 1998; Chopra et al., 2002; Heyns, 2004; McAleer et al., 2002). Approximately 5% to 20% of pediatric patients with blunt trauma will have renal trauma (Fraser et al., 2009).

In a review of the US National Trauma Data Bank, approximately 25% of all renal injuries were in patients younger than 19 years of age (Grimsby et al., 2014). Of these, 90% were blunt trauma injuries, with almost 80% grade 1 to 3 injuries. The mean age for pediatric renal trauma is 14 years, with only 6% younger than 5 years of age and only 2% younger than 1 year of age. Around 20% of patients with grade 4 injuries underwent an open operation, and 50% of those with grade 5 injuries underwent open surgery. Minimally invasive treatments such as angioembolization or ureteral stents were seen in about 5% of all cases with 10% to 15% for grade 4 to 5 injuries. **Nephrectomy for pediatric renal trauma is rare, occurring in around 5% of admissions.** Even though nephrectomy is rare, it may be more common when children are managed in adult trauma units when compared with pediatric trauma units (Grimsby et al., 2014). The most common causes of pediatric renal trauma are motor vehicle collisions, falls, bicycle accidents, and sports-related injuries. All-terrain vehicle accidents as a cause of trauma may be increasing over time (Dangle et al., 2016). **Congenital anomalies such as hydronephrosis or ureteropelvic junction (UPJ) obstruction are three to five times more common in children screened by computed tomography (CT) for trauma than in adults** (Brown et al., 1998; Chopra et al., 2002; Heyns, 2004; McAleer et al., 2002). It is unclear if a congenital anomaly increases the risk for renal injury, and most patients with congenital anomalies such as UPJ obstruction who sustain a renal injury will have lower grade injury (Al-Qudah and Santucci, 2006; Chopra et al., 2002; McAleer et al., 2002).

Presentation

Blunt trauma is the most common cause of pediatric renal trauma with motor vehicle collision, falls, sports injuries, pedestrian versus vehicle, all-terrain vehicle, and motorcycle collisions being some of the most common causes (Ishida et al., 2017; Margenthaler et al., 2002; Nance et al., 2004). **Other organ system injuries are present in about 50% of cases of pediatric blunt renal trauma including liver, spleen, head, or orthopedic injuries** (Ishida et al., 2017; Margenthaler et al., 2002; Nance et al., 2004). History of rapid deceleration, such as from a motor vehicle accident or a fall from height, is associated with renal injuries.

On physical examination, flank tenderness or ecchymosis can be seen in severe renal injuries. Fractured ribs can be found as well. Tachycardia and hypotension can be seen with significant blood loss. **However, in children, sympathetic tone may sustain normal blood pressure longer than in adults, even with significant blood loss, making hypotension a less reliable sign for significant blood loss in renal trauma** (Quinlan and Gearhart, 1990).

Gross or microscopic hematuria can be seen in renal trauma, but the absence of hematuria alone does not rule out significant renal trauma in children (Buckley and McAninch, 2004, 2006; Morey et al., 1996). In many if not most cases of pediatric renal trauma, a urologist is not involved with the decision to obtain imaging or not. Most often, the urologist is called after the diagnosis of renal trauma is made by emergency department or trauma physicians.

Indications for Renal Imaging

In adult patients, the presence of gross hematuria or the presence of microscopic hematuria with hypotension (systolic blood pressure <90 mm Hg) were classically used as indications for evaluation for traumatic genitourinary injury. In adults, these two criteria have a sensitivity of 98% for blunt trauma and 90% for penetrating trauma (Heyns, 2004; Mee et al., 1989; Santucci et al., 2004). However, the specificity of these findings in adults is lower, with only 30% of patients with gross hematuria having an identifiable genitourinary injury and 10% of the patients with microscopic hematuria and shock having an identifiable injury (Heyns, 2004; Mee et al., 1989; Santucci et al., 2004).

In children, the presence of hematuria may be a less sensitive indicator of renal injury. Some studies have found that up to two-thirds of children sustaining a grade 2 or higher renal injury will have a normal urine analysis (Buckley and McAninch, 2004, 2006; Morey et al., 1996). As mentioned earlier, children may maintain their blood pressure with blood loss longer than adults, which would make hypotension a less reliable indicator of significant blood loss from a renal injury (Quinlan and Gearhart, 1990). **Mechanism of injury is an important predictor of renal trauma in children.** A significant deceleration or high-velocity injury such as a fall from greater than 10 feet, motor vehicle collision at high speed, or injury to the abdomen or flank with a foreign object are indications for evaluation of genitourinary injury in children. In addition, associated injuries to thoracic organs or intra-abdominal organs and orthopedic fractures of the ribs, spine, femur, or pelvis are associated with genitourinary trauma in children. When these four criteria (hematuria, hypotension, associated injuries, and mechanism of injury) are used in children as the indications for genitourinary imaging for trauma, they have more than a 98% sensitivity of identifying significant genitourinary injuries (Bartley and Santucci, 2012; Bernard, 2009; Buckley and McAninch, 2011; Herschorn et al., 1991). **Gunshot wounds to the abdomen require evaluation for genitourinary trauma.** In addition, stab wounds to areas near the kidney such as the flank, upper abdomen, or lower chest require imaging to evaluate renal trauma.

In light of the previous information, the American Urological Association (AUA) urotrauma guidelines and the European Association of Urology (EAU) urogenital trauma guidelines recommend obtaining imaging to evaluate for blunt renal trauma if there is gross hematuria, microscopic

hematuria, systolic blood pressure <90 mm Hg, a rapid deceleration injury, a significant blow to the flank injury, or if there are suspicious associated injuries or examination findings (rib fracture, flank ecchymosis, associated abdominal injuries, penetrating injury to abdomen) (Table 52.1) (Kitrey et al., 2018; Morey et al., 2014).

Imaging Studies for Diagnosis

As Low as Reasonably Achievable

The use of CT for evaluation of blunt abdominal trauma is ubiquitous, and several authors have suggested that it is overused for mild trauma in children (Bregstein et al., 2014; Gaither et al., 2018; Streck et al., 2012; Streck et al., 2017). The dose of ionizing radiation from a CT scan is associated with a very small absolute increased risk for subsequent cancers such as leukemia and brain tumors, and the risk increases the younger the age of patient at the time of CT scan (Berrington de Gonzalez et al., 2017; Mathews et al., 2013; Pearce et al., 2012). **Therefore, ALARA (as low as reasonably achievable) is a concept that should be emphasized in pediatric trauma imaging evaluation and follow-up strategies.**

Focused Assessment With Sonography for Trauma

Ultrasonography is an attractive method for evaluating for renal injury because of its wide availability and lack of radiation exposure. The focused assessment with sonography for trauma (FAST) examination has been evaluated as a method for diagnosing renal trauma. Unfortunately, the reported sensitivity is quite variable, with published results ranging from 22% to 96% (Bent et al., 2008; Jang et al., 2004; Lee et al., 2007; McGahan et al., 1999; Nural et al., 2005; Sirlin et al., 2004; Stengel et al., 2015; Suthers et al., 2004; Tsui et al., 2012). When the FAST examination is combined with serial physical examinations for a 24-hour period, a normal FAST examination and normal physical examinations over 24 hours is very good at ruling out any clinically significant renal or intra-abdominal injuries (Bent et al., 2008; Jang et al., 2004; Lee et al., 2007; McGahan et al., 1999; Nural et al., 2005; Sirlin et al., 2004; Suthers et al., 2004; Tsui et al., 2012). **The FAST examination has low sensitivity in diagnosing renal trauma injuries because it is performed in the emergency department, often by emergency department providers, and is usually utilized to look for free fluid in dependent regions of the abdomen and does not specifically evaluate for organ injuries.** None of these studies were done in a pediatric-specific population.

Dedicated Renal Ultrasonography

The comparison of a dedicated renal ultrasonography to CT to diagnose and rule out renal trauma has not been studied extensively in children or adults. In a 2004 prospective study comparing ultrasonography to CT in hemodynamically stable children, ultrasonography missed 2 of 19 (11%) of the renal injuries (Tas et al., 2004). However, the grade or clinical implications of the missed injuries was not given (Tas et al., 2004). In a 2015 study in which 38 patients underwent a focused renal ultrasonography with color Doppler, 35 of 38 patients had a renal injury diagnosed by the ultrasonography. The three patients who were missed had grade 1 renal injuries of likely no clinical significance (Amerstorfer et al., 2015). Given the increasingly nonoperative management of renal trauma and continued focus on limiting radiation exposure in children, more study is needed to define the role of dedicated ultrasonography to diagnose and rule out clinically significant renal trauma. **Because of the lack of studies, the AUA urotrauma guidelines state that ultrasonography can be used for the initial evaluation of renal trauma in children, but CT is preferred** (Morey et al., 2014)**. The EAU pediatric urology guidelines state that ultrasonography can be used as a screening tool for renal injury but that CT scan is the best imaging modality for diagnosis and staging** (Radmayr et al., 2018).

Computed Tomography

For hemodynamically stable patients, CT is currently the most sensitive and specific radiologic test to diagnose and rule out genitourinary trauma. The AUA and EAU trauma guidelines recommend obtaining an IV contrast-enhanced abdominal and pelvic CT scan with immediate and delayed images for the evaluation of renal injury (Kitrey et al., 2018; Morey et al., 2014). In children, a single contrast phase abdominal and pelvic CT scan is often obtained to limit radiation exposure or because of a lack of knowledge about recommended imaging (Fuchs et al., 2018). The obvious limitation of this is that the accuracy in diagnosing urine extravasation and isolated ureteral injuries is decreased, especially in patients with a urinoma or with deep or multiple lacerations (Hardee et al., 2013b). However, in the current era of nonoperative management, some question exists whether obtaining a routine delayed-phase CT in children affects outcomes (Fuchs et al., 2018). In our experience, the radiologist can do a delayed CT phase in real time if there are findings on the nephrogram phase concerning for urine leak (e.g., perinephric fluid collection or deep/multiple renal lacerations), which may avoid unnecessary radiation exposure for the delayed phase (Fuchs et al., 2018; Hardee et al., 2013b; Santucci et al., 2004). **The EAU urogenital trauma guidelines acknowledge that practically, the initial CT scan is often a single phase, and additional phases can be obtained if renal injury is not characterized well enough** (Kitrey et al., 2018).

Classification and Grading of Renal Injuries

AAST Grading System

The American Association for the Surgery of Trauma (AAST) renal organ injury scale (OIS) was created in 1989 and is the most widely used grading system, but a proposed revision was published in 2011 (Table 52.2) (Buckley and McAninch, 2011; Moore et al., 1989). The proposed revision was created to help clarify and classify high-grade renal injuries (grade 4 to 5). The kidney with multiple lacerations into the collecting system (shattered kidney) was moved from a grade 5 classification to a grade 4 classification. In the 2011 proposed revision, only main renal artery or vein laceration or avulsion and main renal artery or vein thromboses are included as grade 5 injuries. Renal pelvic laceration or UPJ disruption injuries were classified in the 2011 revision as grade 4 injuries. The 1989 AAST OIS and the 2011 revised renal injury grading system are shown in Table 52.2. Examples of these injuries are shown in Figs. 52.1 to 52.3. **The AAST OIS grade of injury is associated with need for intervention and risk for developing complications in adults and in children** (Buckley and McAninch, 2011; Grimsby et al., 2014; Margenthaler et al., 2002; Nance et al., 2004; Shariat et al., 2007). As the risk for intervention, complications, and subsequent loss of kidney function is negligible for grade 1 to 3 injuries, some have categorized these as low-grade renal injuries and grade 4 to 5 as high-grade injuries (Au et al., 2016; Dugi et al., 2010; Hardee et al., 2013a; Nerli et al., 2011; Okur et al., 2017; van der Wilden et al., 2013).

TABLE 52.2

Renal Injury: 1989 American Association for the Surgery of Trauma Organ Injury Scale and 2011 Revised Injury Staging Classification

GRADE OF RENAL INJURY	1989 AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA ORGAN INJURY SCALE	2011 PROPOSED REVISION
1	Subcapsular hematoma that is nonexpanding without	Subcapsular hematoma and/or contusion

	laceration Microscopic or gross hematuria with normal urologic studies	No collecting system injury
2	Nonexpanding perirenal hematoma confined to renal retroperitoneum Laceration <1 cm in depth into cortex without urinary extravasation	Laceration <1 cm in depth and into cortex, small hematoma contained within Gerota fascia No collecting system injury
3	Laceration >1 cm into parenchyma without collecting system rupture or urinary extravasation	Laceration >1 cm in depth and into medulla, hematoma contained within Gerota fascia No collecting system injury
4	Parenchymal laceration extending through the renal cortex, medulla, and collecting system Main renal artery or vein injury with contained hemorrhage	One or more lacerations through the parenchyma into the urinary collecting system with urinary extravasation Vascular segmental vein or artery injury Renal pelvis laceration and/or complete ureteropelvic junction disruption
5	Completely shattered kidney Avulsion of renal hilum, which vascularizes kidney	Main renal artery or vein laceration or avulsion Main renal artery or vein thrombosis

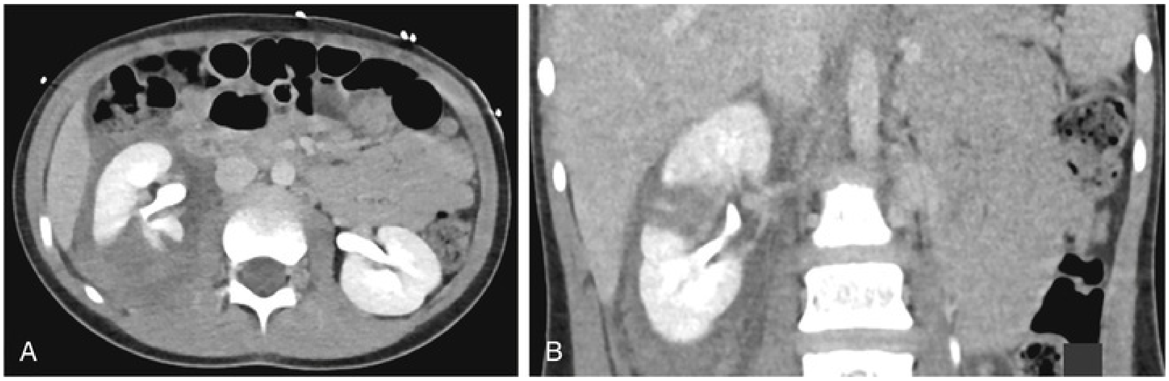

FIG. 52.2 (A) Grade 3 right renal laceration on delayed phases. (B) Laceration greater than 1 cm in depth but no extravasation of contrast on delayed phase.

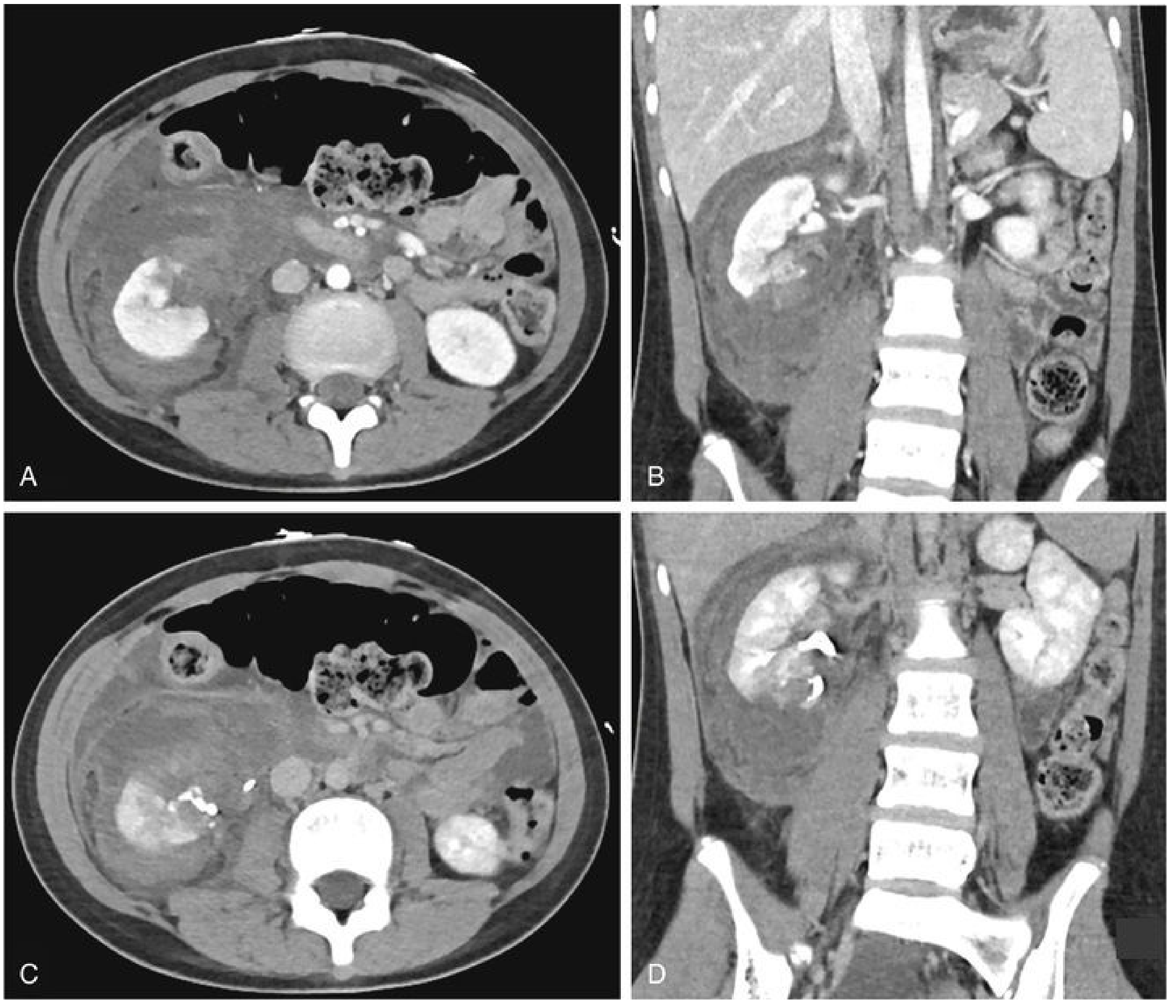

FIG. 52.3 Grade 4 right renal laceration. Immediate contrast phases show laceration (A and B) with delayed phases showing extravasation of contrast from collecting system (C and D).

High-Risk Criteria

Some specific findings for grade 4 to 5 injuries on CT scan are associated with subsequent intervention. **Medial extravasation of contrast is worrisome for possible ureteropelvic junction disruption and is associated with intervention** (Al-Qudah and Santucci, 2006; Bartley and Santucci, 2012; Kawashima et al., 1997)**. Lack of contrast seen in the ureter in the setting of grade 4 injury is associated with subsequent intervention for urine leak in pediatric series** (Au et al., 2016; Cannon et al., 2008)**. If greater than 25% of renal parenchyma is devitalized, this has been associated with a significantly higher rate of angioembolization and open surgery** (Long et al., 2013). A large perirenal hematoma (>3.5 cm), vascular contrast extravasation, and medial renal laceration have been associated with undergoing procedure for bleeding such as angioembolization (Charbit et al., 2011; Dugi et al., 2010; Figler et al., 2013; Hardee et al., 2013a; Lin et al., 2013; Nuss et al., 2009). The risk for intervention has been associated with the number of these risk factors present (perirenal hematoma greater than 3.5 cm, vascular extravasation, and medial laceration), with 1 or fewer risk factors having less than 10% intervention risk and two to three risk factors having greater than 50% risk for intervention (Dugi et al., 2010; Figler et al., 2013; Hardee et al., 2013a). These high-risk criteria have also been associated with intervention in children and with perirenal hematoma greater than 2.2 cm associated with intervention (Lee et al., 2016). These high-risk criteria are important predictors of intervention in high-grade renal trauma, and many leaders in the field recommend revision of the AAST OIS to reflect these findings (Chiron et al., 2016; Dugi et al., 2010; Figler et al., 2013; Hardee et al., 2013a). Reported high-risk criteria are shown in Table 52.3, and examples of these findings on CT imaging are shown in Fig. 52.4.

TABLE 52.3

High-Risk Criteria for Intervention in Grades 4 to 5 Renal Injuries

Large perirenal hematoma (>3.5 cm for adults, >2.2 cm for children)
Vascular contrast extravasation
Medial renal laceration
>25% of renal parenchyma devitalized
Medial extravasation of urine during excretory phase
Urine extravasation and lack of contrast seen in distal ureter during excretory phase

Blunt Versus Penetrating

The distinction between blunt and penetrating genitourinary trauma affects the decision to obtain imaging and pursue surgical exploration. **In general, any significant penetrating injury to the abdomen, flank, or lower chest should lead to an evaluation for genitourinary trauma** (Kitrey et al., 2018; Morey et al., 2014). This applies to patients with penetrating abdominal injury who are hemodynamically stable and without hematuria (Kitrey et al., 2018; Morey et al., 2014). If a patient with penetrating abdominal trauma is unstable or has other injuries that require repair and an exploratory laparotomy is performed, the retroperitoneum and ureters should be inspected, and surgeons should have a high index of suspicion for renal or ureteral injury, especially with high-velocity gunshot wounds.

Management

The majority of pediatric renal trauma is managed nonoperatively, and this is a strong recommendation by the EAU pediatric urology guidelines (Ishida et al., 2017; LeeVan et al., 2016; Margenthaler et al., 2002; Nance et al., 2004; Radmayr et al., 2018). The vast majority of grade 1 to 3 injuries do not require any intervention, let alone open surgery (Buckley and McAninch, 2011; Grimsby et al., 2014; Ishida et al., 2017; LeeVan et al., 2016; Margenthaler et al., 2002; Nance et al., 2004; van der Wilden et al., 2013). Grade 4 and 5 injury patients have a higher risk for undergoing an intervention (Au et al., 2016; Buckley and McAninch, 2011; Eassa et al., 2010; Grimsby et al., 2014; Richards et al., 2017; van der Wilden et al., 2013). **The interventions most often required are endoscopic or percutaneous, such as percutaneous nephrostomy tube, ureteral stent, percutaneous drain placement, and angioembolization** (Au et al., 2016; Buckley and McAninch, 2011; Eassa et al., 2010; Grimsby et al., 2014; Ishida et al., 2017; Margenthaler et al., 2002; Nance et al., 2004; Richards et al., 2017; van der Wilden et al., 2013).

Nonoperative

In addition to numerous publications in adults supporting nonoperative management of renal trauma, several publications have confirmed the safety and efficacy of nonoperative management for renal trauma in children (Broghammer et al., 2006; Henderson et al., 2007; Ishida et al., 2017; LeeVan et al., 2016; Margenthaler et al., 2002; Nance et al., 2004; Richards et al., 2017; Tsui et al., 2012). **The nephrectomy rate has been reported to be higher with surgical exploration than with nonoperative management in multiple series in adults and one series in children** (Jacobs et al., 2012). For a patient to be eligible for a nonoperative management protocol, they must either be hemodynamically stable or able to be resuscitated adequately and remain stable after resuscitation. **The**

ideal candidate for a nonoperative management protocol is a patient with a grade 1 to 3 injury from blunt trauma who has no other associated injuries that require surgery and is hemodynamically stable. However, even children with grade 4 to 5 injuries have been successfully managed nonoperatively with series reported from several centers (Au et al., 2016; Eassa et al., 2010; Henderson et al., 2007; LeeVan et al., 2016; Nerli et al., 2011; Okur et al., 2017; Umbreit et al., 2009). In addition, nonoperative management of penetrating renal trauma has favorable outcomes (Bjurlin et al., 2011; Moolman et al., 2012; Wessells et al., 1997).

Nonoperative Management Protocol

The first steps in nonoperative management are to confirm lack of hemodynamic instability and grade the renal injury. The AUA and EAU guidelines state that in children a dedicated renal ultrasonography is an option, but a contrast-enhanced CT scan of the abdomen and pelvis with immediate and delayed phases is preferred (Kitrey et al., 2018; Morey et al., 2014; Radmayr et al., 2018). However, perhaps in the future, dedicated renal ultrasonography will be enough to confirm the absence of a significant retroperitoneal hematoma, deep laceration, or urinoma and thereby avoid CT in certain stable patients with grade 1 to 3 renal injuries (Amerstorfer et al., 2015; Tas et al., 2004). At our institution, the patient is placed on bed rest, serial hemoglobin/hematocrit measurements are obtained, and an abdominal examination is performed. Bed rest is typically continued until gross hematuria has resolved and blood counts have remained stable. The duration of bed rest and intensity of observation varies by injury severity. A grade 1 to 2 renal injury without gross hematuria and no decline in hemoglobin/hematocrit may require only a 23-hour observation with two serial blood tests. At the other end of the spectrum, a grade 4 renal injury with a large perirenal hematoma with vascular contrast extravasation on CT scan and ongoing gross hematuria may require Intensive Care Unit admission, blood draws every 4 to 6 hours, potential blood transfusions, and most likely angioembolization.

Early Repeat Imaging

The AUA urotrauma guidelines recommend a repeat contrast-enhanced CT scan of the abdomen and pelvis 48 hours after injury for grade 4 to 5 injuries, but the

EAU urogenital trauma guidelines state that repeat imaging can be omitted for grade 1 to 4 injuries as long as there are no clinical concerns for missed complication (Kitrey et al., 2018; Morey et al., 2014). In children, there is more attention on avoiding unnecessary radiation from CT scans and adhering to the ALARA concept. If the patient is stable and doing well on nonoperative management, it is unclear what utility a repeat CT scan has over dedicated renal ultrasonography (Canon et al., 2014; Eeg et al., 2009; Gaither et al., 2018). At our institution, we typically obtain follow-up renal ultrasonography in 48 to 72 hours for a high-grade injury instead of repeat abdominal CT, and we only obtain a repeat abdominal CT scan if the renal ultrasound scan does not provide enough information to guide clinical management. However, even the utility of routine repeat ultrasonography in 48 hours in grade 4 to 5 injuries has been called into question if the patient is stable and doing well on nonoperative management without apparent complications (Canon et al., 2014).

Outcomes of Nonoperative Management

Several series in the adult literature and one series in children have shown a lower nephrectomy rate with nonoperative management compared with the operative approach (Broghammer et al., 2007; Cass and Ireland, 1973; Cass et al., 1987; Hammer and Santucci, 2003; Jacobs et al., 2012; Kristjansson and Pedersen, 1993). In children, several series have also shown that the vast majority of renal trauma cases can be managed nonoperatively (Broghammer et al., 2006; Henderson et al., 2007; Ishida et al., 2017; LeeVan et al., 2016; Margenthaler et al., 2002; Nance et al., 2004; Richards et al., 2017; Tsui et al., 2012). **The risk for intervention is significantly higher in grade 4 to 5 injuries and penetrating injuries, but these patients can be managed successfully nonoperatively in the majority of patients who are hemodynamically stable** (Bjurlin et al., 2011; Buckley and McAninch, 2011; Eassa et al., 2010; Grimsby et al., 2014; Henderson et al., 2007; Kansas et al., 2004; Moolman et al., 2012; Nerli et al., 2011; Okur et al., 2017; van der Wilden et al., 2013; Wessells et al., 1997).

Management of Complications in Nonoperative Patients

Patients on a nonoperative management protocol may develop complications, and urologists need to be aware of the management issues. The risk for complications increases with grade of injury and is close to 0% for grade 1 to 2 injuries and for grade 3 injuries without devitalized segments. Hemodynamically stable patients with grade 3 injuries with devitalized segments to grade 5 injuries have around a 25% risk for bleeding requiring angioembolization and a 15% risk for urinoma requiring intervention. **Only around 5% of patients will undergo open surgical exploration for a complication that cannot be managed nonoperatively or with percutaneous/endoscopic intervention** (Cannon et al., 2008; Dangle et al., 2016; Eassa et al., 2010; Hammer and Santucci, 2003; Henderson et al., 2007; Ishida et al., 2017; LeeVan et al., 2016; Nance et al., 2004; Nerli et al., 2011; Okur et al., 2017; Richards et al., 2017; Santucci et al., 2004; Tsui et al., 2012; Umbreit et al., 2009; van der Wilden et al., 2013).

Persistent Urine Leak

By definition, grade 1 to 3 injuries do not have a laceration into the collecting system, and grade 4 to 5 injuries can have urine leaks. The most common location for a urine leak is at a renal laceration site, but it can be seen from a renal pelvis rupture, ureteral injury, or UPJ disruption. **The AUA urotrauma and EAU urogenital trauma guidelines state that renal injuries with a urine leak can be managed nonoperatively** (Kitrey et al., 2018; Morey et al., 2014). In patients with urine leak, it is important to evaluate the renal pelvis and ureter for UPJ disruption injury and renal pelvis rupture. This can be done by CT scan with delayed images or by retrograde pyelography.

Although most urine leaks from renal lacerations can be managed without intervention, some will require percutaneous drainage of the urinoma or diversion of the urine away from the urine leak with either percutaneous nephrostomy tube and/or ureteral stent. It is estimated that up to 85% of urine leaks will resolve spontaneously and not have an intervention (Alsikafi et al., 2006; Henderson et al., 2007; Umbreit et al., 2009). It is unclear if a Foley catheter improves the chances or speed of urine leak resolution, but is often placed to facilitate bladder drainage for 2 to 3 days initially after the trauma. In addition, the use of IV antibiotics (typically IV cefazolin) is commonly used when there is a urine leak, but there is no published data showing that this practice decreases infectious complications.

Indications for Intervention for Urine Leak or

Urinoma

The classic triad of a symptomatic persistent urinoma after renal trauma is ipsilateral flank pain, ileus, and low-grade fever. Clearly, some urinomas are more symptomatic than others, and we recommend use of shared decision making with patients and families rather than a strict algorithm when deciding whether to intervene or continue observation for symptomatic urinomas. A very large, symptomatic urinoma may be best managed by early intervention, and a small, mildly symptomatic urinoma can be observed longer and potentially avoid intervention.

Another indication for evaluation and potential intervention is urine leak with no contrast seen in the distal ureter on the urogram phase of CT. This could be a UPJ disruption or significant injury to the renal pelvis, which may need immediate repair or at least urine drainage (Au et al., 2016; Kawashima et al., 1997). Therefore, a cystoscopy with retrograde pyelography is recommended for evaluation (Fig. 52.5). If the retrograde pyelogram does not show UPJ disruption or renal pelvis laceration, some recommend ureteral stent placement in this situation. This recommendation is based on the observation that patients with urine leak after renal trauma and no contrast seen in ipsilateral ureter at time of initial CT scan are at higher risk for developing symptomatic urinoma if they do not have a ureteral stent placed (Au et al., 2016; Cannon et al., 2008).

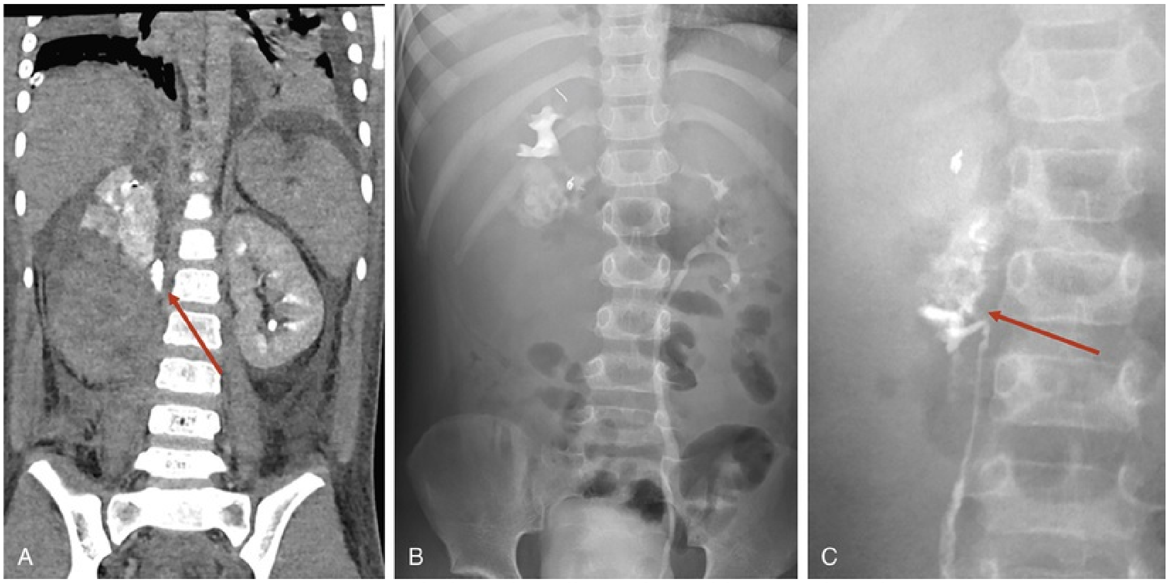

FIG. 52.5 Ureteropelvic junction disruption with associated renal parenchymal injury. There is medial extravasation of contrast *(red arrow)* and significant amount of devitalized parenchyma on the right lower pole

(A). An intravenous pyelogram failed to show any contrast in the right ureter (B); note the coil from selective angioembolization is also visible. Retrograde pyelogram confirmed ureteropelvic junction disruption *(red arrow)* (C).

Ureteral Stent

Based on expert opinion, the AUA urotrauma guidelines recommend starting with a ureteral stent if the intervention is performed for a urine leak or urinoma and augmenting urine drainage with percutaneous drainage if needed (Morey et al., 2014). **The EAU guidelines state that ureteral stent placement and/or percutaneous drainage often leads to resolution of urinary extravasation** (Kitrey et al., 2018). Placement of a ureteral stent and Foley catheter has been reported to resolve 90% of symptomatic urinomas (Alsikafi et al., 2006; Au et al., 2016; Reese et al., 2014; Umbreit et al., 2009). We typically leave the Foley catheter for 1 to 2 days after symptoms from urinoma have resolved, evaluate urinoma size with renal ultrasonography, remove the Foley catheter, and observe for at least another day for recurrent symptoms. Although the Foley catheter is in place, IV Ancef is often given, but this is not based on any good guidance from literature. The ureteral stent is then removed 4 to 6 weeks later, with consideration given to renal ultrasonography before removal. We often use prophylactic antibiotics while the ureteral stent is in place, but it is unclear if this is necessary.

The advantages of using ureteral stents include their minimally invasive nature and the lack of any external drainage tubes or devices that can be dislodged, which can be an issue in the pediatric population. The disadvantages of ureteral stents are the need for anesthesia for placement and removal in the pediatric population; symptoms from indwelling double-*J* ureteral stents can be quite bothersome, especially to pubertal patients; there is a potential for clogging or blockage; and it can be more difficult to determine if a urine leak has resolved compared to a percutaneous drain.

Percutaneous Drain

Placement of a percutaneous drain into the urinoma is another intervention for symptomatic urinomas. This is often used if a ureteral stent does not lead to resolution of symptoms from a urinoma, especially a very large urinoma.

However, it can be used as the first intervention for a urinoma (Russell et al., 2001; Umbreit et al., 2009). Fig. 52.6 shows a case of a symptomatic urinoma treated by percutaneous drain placement without Foley catheter placement that led to resolution in 3 days. The drain was then removed without anesthesia. If the family elects to proceed with percutaneous drain placement initially, we discuss Foley catheter placement as a method to potentially facilitate drainage as well. Drain output is followed, and the drain is removed once output is minimal and renal ultrasonography shows resolution of urinoma. The need for repeat renal ultrasonography to ensure urinoma resolution if symptoms have resolved is unclear but is typically obtained.

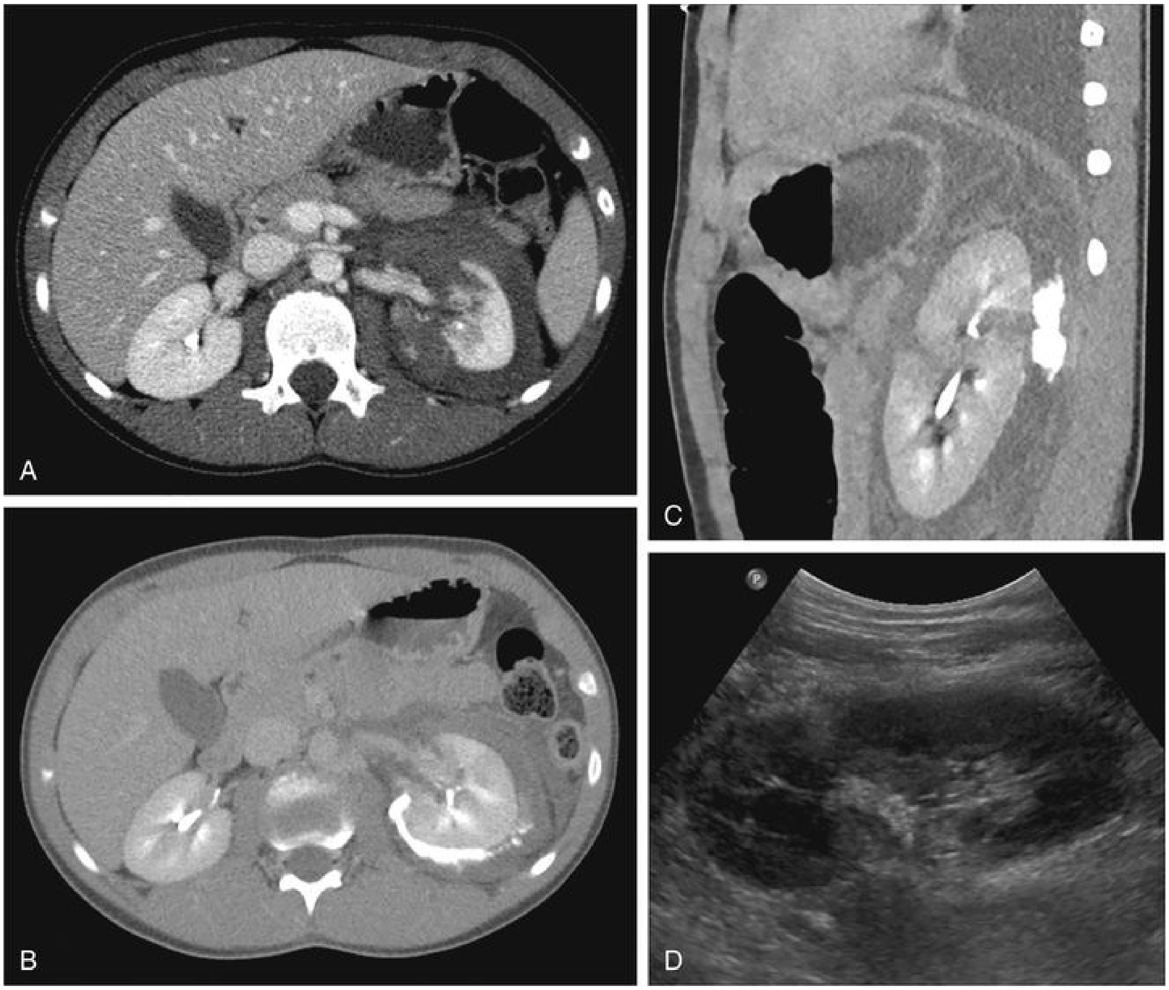

FIG. 52.6 Grade 4 renal laceration managed with percutaneous drain into urinoma only. Initial CT scan day of injury showing contrast extravasation (A and B). Repeat CT scan 2 days later obtained because of fever and worsening abdominal pain showing atelectasis in left lung and persistent extravasation of contrast (C). Percutaneous drain placed and removed 3

days later with follow-up ultrasonography 2 months in future (D).

The advantages of percutaneous drain placement are rapid resolution of symptoms from the urinoma, ability to monitor output from the drain, and ability to remove the drain without the need for anesthesia. The disadvantages of percutaneous drain placement include the need for anesthesia and interventional radiology for placement, the possibility of dislodgement, and the possible need for a ureteral stent.

Nephrostomy Tube

Nephrostomy tube placement is another method for diverting urine away from a urine leak. We favor ureteral stent placement or percutaneous drain into a urinoma initially over nephrostomy tube placement because of the risk for kidney injury and bleeding with nephrostomy tube placement. **Nephrostomy tube placement alone is rarely used for symptomatic urinoma and urine leak.** Nephrostomy tube placement combined with antegrade ureteral stent placement has a high resolution rate for symptomatic urinomas (Al-Qudah and Santucci, 2006; Umbreit et al., 2009). In a patient with persistent urine leak after ureteral stent placement and percutaneous drain placement into a urinoma, we consider nephrostomy tube placement. Also, in a patient who cannot be placed in the lithotomy position because of other injuries, a nephrostomy tube with antegrade ureteral stent placement is an option.

Angioembolization of Isolated Renal Segment

In persistent urine leaks from an isolated renal parenchymal segment not in continuity with the rest of the collecting system that fails to resolve with ureteral stent placement, nephrostomy, and percutaneous urinoma drain, angioembolization of the isolated renal segment is a useful option. This is a very rare situation to encounter, but some have reported success with this technique (Akbari et al., 2016; Pinto and Chimeno, 1998).

Renal Exploration With Repair of Urine Leak

The need for renal exploration to repair a urine leak from a renal laceration is thankfully quite rare as most resolve with observation or minimally invasive procedures, however, it has been reported (Henderson et al., 2007; Lee et al., 2016; Long et al., 2013; Reese et al., 2014). **Open repair would only be considered after a significant period of observation for the urine leak and multiple minimally invasive procedures.** Principles of repair would be to debride any devitalized tissue, close the collecting system with absorbable sutures, repair the renal parenchyma over a bolster, and adequately drain with a ureteral stent and perinephric drain. The risk for renal loss or nephrectomy should be discussed with the patient and family.

Persistent or Delayed Bleeding

Indications for Angioembolization

Around 25% of grade 3 to 5 renal injuries managed nonoperatively will have persistent bleeding or develop a delayed bleed that requires an intervention (Al-Qudah and Santucci, 2006; Kansas et al., 2004; LeeVan et al., 2016). As stated earlier, high-risk criteria such as perirenal hematoma size, vascular contrast extravasation, and medial renal laceration are risk factors for needing angioembolization in high-grade renal injuries (Dugi et al., 2010; Figler et al., 2013; Hardee et al., 2013a). Persistent bleeding after injury is typically caused by the injured blood vessels failing to tamponade. Delayed bleeding can be caused by the development of an arteriovenous fistula or a pseudoaneurysm in an injured artery that ruptures after a period. Some theorize that resolution or liquification of the hematoma that was tamponading the arteriovenous fistula or pseudoaneurysm leads to the delayed bleed. **Delayed bleeds typically develop 1 to 2 weeks postinjury but can occur up to 1 month postinjury.**

For persistent bleeding in a hemodynamically stable patient, we typically allow a patient to receive two to three blood transfusions before recommending angioembolization. However, if a patient is having trouble maintaining stable blood pressure, is transiently hemodynamically unstable from active bleeding, or we are concerned about rapid bleeding, more urgent angioembolization is undertaken. In some series, most cases of delayed bleeding require intervention to resolve (Goffette and Laterre, 2002). Therefore, when a patient presents with a delayed bleed after renal trauma, we are more likely to recommend early angioembolization unless the bleeding is mild and stopped spontaneously.

Superselective angioembolization has a high success rate for resolution of persistent and delayed bleeding, with most series reporting over 80% success in adults and children (Au et al., 2016; Breyer et al., 2008; Eassa et al., 2010; Henderson et al., 2007; LeeVan et al., 2016; Mohsen et al., 2008; Nance et al., 2004; Reese et al., 2014; Umbreit et al., 2009)**. Even if initial angioembolization is not successful, a repeat angioembolization can be performed with success** (Hotaling et al., 2011; Mohsen et al., 2008). The procedure is typically performed by interventional radiologists, and the goal is to embolize the smallest amount of viable parenchyma and still stop bleeding. Even with superselective embolization, some functional renal parenchyma will likely be lost (Mohsen et al., 2008). The amount of preserved renal function lost depends on the degree of initial injury and the embolization procedure, but the retained differential renal function after grade 4 injuries has been reported at 35% to 45% and after grade 5 injuries at 10% to 30% (Fiard et al., 2012; Keller et al., 2004; Tasian et al., 2010).

Complications of renal angioembolization include postembolization syndrome, persistent bleeding, and postembolization abscess. **Postembolization syndrome is a self-limited condition, which includes flank pain, fever, and possible ileus and occurs in less than 10% of these patients. The symptoms typically resolve within 3 to 4 days** (Breyer et al., 2008)**. If the fever persists, evaluation for postembolization abscess is indicated.** Repeat CT is usually the best way to evaluate for postembolization abscess, and placement of a drain into any concerning fluid collection could then be performed. Persistent or recurrent bleeding can be seen in a minority of cases after angioembolization (Breyer et al., 2008). Repeat angioembolization is usually successful, and this is what we recommend if the patient is hemodynamically stable (Hotaling et al., 2011; Mohsen et al., 2008). However, if bleeding persists after repeat angioembolization, the need for renal exploration should be considered.

Renal Exploration

Renal exploration for persistent or delayed bleeding during initial nonoperative management of a renal injury occurs in a small percentage of cases (LeeVan et al., 2016; Umbreit et al., 2009; van der Wilden et al., 2013). The goals of exploration at this time are similar to the goals of renal exploration for unstable patients at the time of initial presentation, but patients are typically more stable. **The goals include isolation and control of renal vasculature, complete exposure of the area of injury, debridement of any devitalized tissue, closure of collecting system defects, closure of renal parenchyma over a bolster, and adequate drainage of the area.**

Key Points: Nonoperative Management and Complications During Nonoperative Management

- The majority of renal trauma can be managed nonoperatively. Grade 4 to 5 injuries can be managed nonoperatively but have higher risk for intervention.

- Around 25% of patients with grade 3 to 5 injuries being managed nonoperatively will have persistent or delayed bleeding. Superselective angioembolization of bleeding vessels is very successful and is the preferred method for management. Repeat angioembolization can also be successful if the initial attempt fails.
- Approximately 15% of patients with a urine leak being managed nonoperatively will have an indication for intervention such as ureteral stent placement and/or percutaneous drain placement.
- Repeat CT imaging 48 to 72 hours after injury is not needed for patients with grade 1 to 3 injuries who are recovering without complication. Repeat CT imaging in 48 to 72 hours may be obtained in patients with grade 4 to 5 injuries but is of unclear utility if the patient is recovering without apparent complication.

Operative

Indications

The primary indication for renal exploration is persistent hemodynamic instability caused by renal bleeding. If, at the time of surgical exploration of an unstable patient without prior imaging, a pulsatile and expanding retroperitoneal hematoma is found, that kidney should be explored due to evidence of persistent renal bleeding leading to the hemodynamic instability (Kitrey et al., 2018). **Another indication for operative intervention is a patient with known renal bleeding that cannot be controlled by selective angioembolization.** In an unstable patient with an inadequately staged renal trauma or a renal trauma with known devitalized segments at the time of exploration who is found to have a nonpulsatile retroperitoneal hematoma, the decision to explore that kidney is less clear. In the past, some have advocated for renal exploration for those with a nonpulsatile hematoma at time of exploratory laparotomy in the setting of penetrating trauma or when there are known devitalized segments in grade 3 to 5 injuries (Kansas et al., 2004; Santucci et al., 2004). Most recent reports recommend not proceeding with renal exploration in the setting of a stable hematoma even in the setting of gunshot wounds as the nephrectomy rate may be lower (Bjurlin et al., 2011; Rostas et al., 2016). In addition, more recent reports have indicated that higher grade injuries in children can be managed nonoperatively (Eassa et al., 2010; Henderson et al., 2007; LeeVan et al., 2016; Nerli et al., 2011; Okur et al., 2017). The AUA urotrauma and EAU urogenital trauma guidelines do not specifically offer recommendations for these scenarios (Kitrey et al., 2018; Morey et al., 2014). If there is an obvious injury to another organ leading to blood loss and hemodynamic instability in a patient with a nonpulsatile retroperitoneal hematoma who has not had a prior CT scan, it would seem prudent to avoid renal exploration.

One-Shot intraoperative Intravenous Pyelography or Ultrasonography

If the presence of a contralateral kidney has not been confirmed by preoperative imaging, this information can be obtained by one-shot intraoperative intravenous pyelography (IVP) (Heyns, 2004; Santucci et al., 2004). Classically, one-shot IVP involves 2 mL/kg intravenous bolus of contrast followed by a radiograph taken 10 to 15 minutes later. The IVP may only inform the surgeon whether or not there is a contralateral kidney present and will not grade any injury accurately. This information may help guide decision making in the situation in which renal exploration with nephrectomy versus attempts at renal reconstruction is being considered intraoperatively. Intraoperative renal ultrasonography with Doppler may be another option to confirm a contralateral kidney with good blood flow but has not been reported on or recommended as frequently as one-shot IVP.

Control of Renal Vasculature

When renal exploration for trauma was more common, the method and timing of control of the renal vessels was a topic of interest. Some advocated for early control of vessels through an incision in the mesentery medial to the inferior mesenteric vein to identify the aorta and renal vessels as a way to decrease nephrectomy risk (Carroll et al., 1989, 1994; McAninch et al., 1991). In addition, retrospective series with early vascular control seemed to have lower nephrectomy rates than series without early vascular control (Atala et al., 1991; Carroll et al., 1989, 1994; Corriere et al., 1991; McAninch et al., 1991). One randomized trial between early vascular control and no early vascular control did not show a difference in nephrectomy rates, and the early vascular control group had longer operative times (Gonzalez et al., 1999). Early control of vessels would seem wise for a hemodynamically unstable patient with an expanding retroperitoneal hematoma; however, the AUA urotrauma and EUA urogenital trauma guidelines do not address this topic (Kitrey et al., 2018; Morey et al., 2014). For early control of vessels, an incision in the posterior mesentery medial to the inferior mesenteric vein over the aorta is made, and vessel loops are applied around the renal vessels and tightened if needed.

Reconstruction Versus Nephrectomy

In addition to stopping life-threatening hemorrhage, one goal of renal exploration should be to save and reconstruct the kidney whenever feasible and safe for the patient (Kitrey et al., 2018). If the presence of a contralateral kidney has not been confirmed by CT imaging, on-table IVP or ultrasonography can be used to do this before renal exploration. After opening up Gerota fascia, vascular control of the main renal arteries and veins should be obtained if this has not been done. The kidney should be freed up so the entire area of injury is exposed, which may require exposure of the entire kidney. Any devitalized tissue should be debrided. Any bleeding parenchymal vessels should be oversewn with absorbable suture and any holes in the collecting system closed with absorbable suture. Small renal defects can be closed by placing large absorbable sutures through the renal capsule. Larger renal defects are typically closed after packing the defect with hemostatic bolsters or omentum. For closure of larger defects, we like to use bolsters of hemostatic agents and to close the defect over the bolster using the sliding clip technique; however, many different techniques for renorrhaphy are available (Benway et al., 2010). If the renal injury is too severe to repair or would leave a very small portion of remaining kidney, nephrectomy should be performed. In addition, if the patient is unstable and it is safest to expedite surgery with nephrectomy to save the life of the patient because of hypothermia, coagulopathy, or ongoing blood loss, nephrectomy should be performed. In a penetrating injury, especially high-velocity gunshot wounds, it is important to inspect the ipsilateral ureter for any injury and repair if found.

Renal Arterial Laceration

Because the kidney does not have good collateral arterial flow, whatever renal segments that are devitalized by an arterial injury typically are not salvageable. If the main renal artery is avulsed or injured and bleeding significantly, the surviving patient will be hemodynamically unstable and should be explored with an anticipated nephrectomy. In fact, attempts to repair these types of injuries are associated with poorer outcomes (Knudson et al., 2000; Turner et al., 1983). In a patient with a solitary kidney or bilateral renal arterial injuries, consideration should be given to an attempt at renal artery injury repair (Kitrey et al., 2018). Vascular surgery consultation should be obtained if available for these rare situations.

Renal Arterial Occlusion

Another type of renal artery injury is complete or partial occlusion of renal arterial flow after blunt trauma caused by renal artery embolism or an intimal flap. This type of injury has been observed successfully, but a postinfarction syndrome with fever and flank pain may be expected, and these patients should be followed for the development of hypertension (Jawas and Abu-Zidan, 2008; Xu et al., 2017). Exploration with nephrectomy may be considered for uncontrolled pain or infection in a patent who is being observed. In more than 50 reported cases, percutaneous renal artery revascularization by interventional radiologists with angioplasty and/or endovascular stenting has been reported to successfully salvage some kidneys with completely occluded or partially occluded renal arteries after blunt trauma (Jahangiri et al., 2017).

Ureteropelvic Junction Disruption

Ureteropelvic junction disruption is a rare renal injury but is important not to miss (Murphy et al., 2017)**. This injury is associated with high-velocity acceleration/deceleration injuries and hyperextension of torso** (Palmer and Drago, 1981; Pesenti et al., 2016; Slobogean et al., 2007). A rapid change in position of the more mobile kidney away from the more fixed proximal ureter is thought to be the pathophysiology. Because of the severity of the mechanism of injury, we and others have seen patients with UPJ disruption having Chance fractures (flexion/extension crush injury to the anterior part of the vertebra and transverse fracture through the posterior part of vertebra) and other significant injuries to intra-abdominal organs such as the aorta and duodenum (Brandes et al., 2004; Dar et al., 2017; Palmer and Drago, 1981; Pereira et al., 2010; Pesenti et al., 2016; Slobogean et al., 2007). Many patients with a UPJ disruption injury will have significant enough associated injuries that an exploratory laparotomy is performed, often without preoperative imaging (Al-Qudah and Santucci, 2006; Chopra et al., 2002; McAleer et al., 2002). The urine analysis usually shows some degree of hematuria, but a significant minority of cases do not demonstrate hematuria (Al-Qudah and Santucci, 2006; Brandes et al., 2004; Chopra et al., 2002; Dar et al., 2017; McAleer et al., 2002). **Because of these factors, the diagnosis of UPJ disruption is often delayed, which can lead to complications that could lead to significant morbidity and mortality such as retroperitoneal abscess, fistula, or infected urinoma** (Boone et al., 1993; Brandes et al., 2004; Pereira et al., 2010). Persistent postoperative fever, ileus, flank pain, urine leaking from intra-abdominal drains, or increasing urinoma will lead to repeat CT scan and subsequent diagnosis of UPJ disruption.

The classic findings suggestive of UPJ disruption on CT scan include medial extravasation of contrast near the ureteropelvic junction, lack of contrast in the distal ureter, and lack of renal parenchymal laceration (Al-

Qudah and Santucci, 2006; Boone et al., 1993; Chopra et al., 2002; Dar et al., 2017; McAleer et al., 2002; Pesenti et al., 2016; Slobogean et al., 2007). Fig. 52.7 shows an example of bilateral UPJ disruption with minimal parenchymal laceration. Renal parenchymal lacerations can be seen in our experience, and the presence of a laceration does not exclude UPJ disruption (see Fig. 52.5). If there is any suspicion for UPJ disruption, retrograde pyelography should be performed.

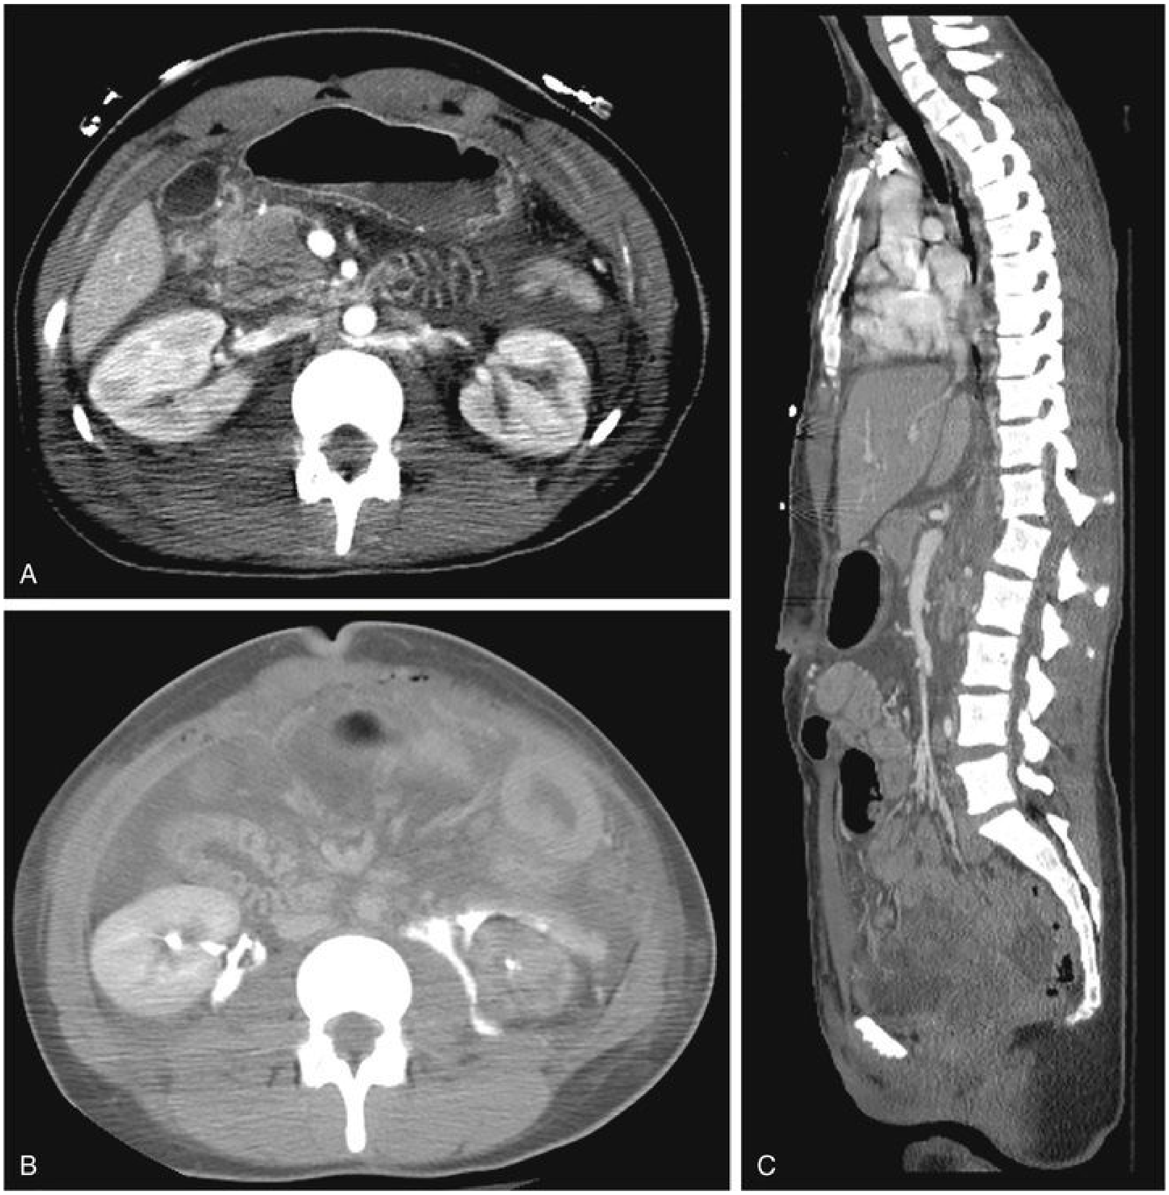

FIG. 52.7 Bilateral ureteropelvic junction disruption injury after a high-velocity motor vehicle collision. Nephrogram phase of CT scan showed only minimal lacerations (A). Delayed phase of CT showed medial

extravasation of urine bilaterally (B). Associated Chance type fracture at T12–L1 with malalignment of vertebral bodies in this area (C).

The management of UPJ disruption depends on the clinical stability of the patient and timing of diagnosis. In a clinically stable patient in whom the diagnosis is made within a few days of the injury, immediate exploration with repair of the UPJ disruption may be preferred (Boone et al., 1993; Brandes et al., 2004; Dar et al., 2017; Pereira et al., 2010)**. Immediate repair of ureteral injuries in stable patients at time of laparotomy is recommended by the AUA urotrauma and EAU urogenital trauma guidelines** (Kitrey et al., 2018; Morey et al., 2014). This surgery is difficult as the renal pelvis is typically not dilated, and good exposure is essential. Debridement of any nonviable ureter and renal pelvis should be performed followed by a spatulated, tension-free anastomosis of the ureter to the renal pelvis. Mobilization of the kidney downward may be needed for a tension-free anastomosis. We recommend doing the repair over a double-*J* ureteral stent left in place for 4 to 6 weeks and over a retroperitoneal drain left in place for several days. A nephrostomy tube could also be considered based on surgeon preference or if repair was tenuous. In a clinically unstable patient, a patient who cannot be positioned for surgery because of orthopedic injuries, or when the diagnosis is delayed more than 1 week, placement of a nephrostomy tube and retroperitoneal drain with delayed repair of the UPJ disruption is recommended by most and is suggested by AUA urotrauma guidelines for delayed ureteral injuries (Morey et al., 2014). Although there is little guidance from literature, we would recommend delayed repair about 2 to 3 months after drain placement. The delayed surgery follows the same principles as the immediate surgery, but scar tissue in the area of the renal pelvis and proximal ureter may make the surgery more difficult. Nephrectomy should always be mentioned to families as a possibility if a repair is not possible.

Renal Pelvis Rupture

Renal pelvis rupture is a rare finding after renal trauma (Ashebu et al., 2004; Hall and Carpinito, 1994; Li et al., 2007; Murawski et al., 2008; Taken et al., 2015). It may be more common in patients with pre-existing hydronephrosis and UPJ obstruction, but this is unclear given how rarely renal pelvis rupture occurs (Ashebu et al., 2004; Hall and Carpinito, 1994; Li et al., 2007). Cases have been managed successfully with an indwelling ureteral stent, and others have undergone operative repair (Ashebu et al., 2004; Hall and Carpinito, 1994; Li et al., 2007; Murawski et al., 2008; Taken et al., 2015). Some cases with pre-existing UPJ obstruction have been managed by delayed pyeloplasty after healing of the urine leak (Ashebu et al., 2004; Hall and Carpinito, 1994; Li et al., 2007). Fig. 52.8 shows a case of renal pelvis rupture managed by ureteral stent, percutaneous drain into urinoma, and delayed robotic-assisted laparoscopic pyeloplasty.

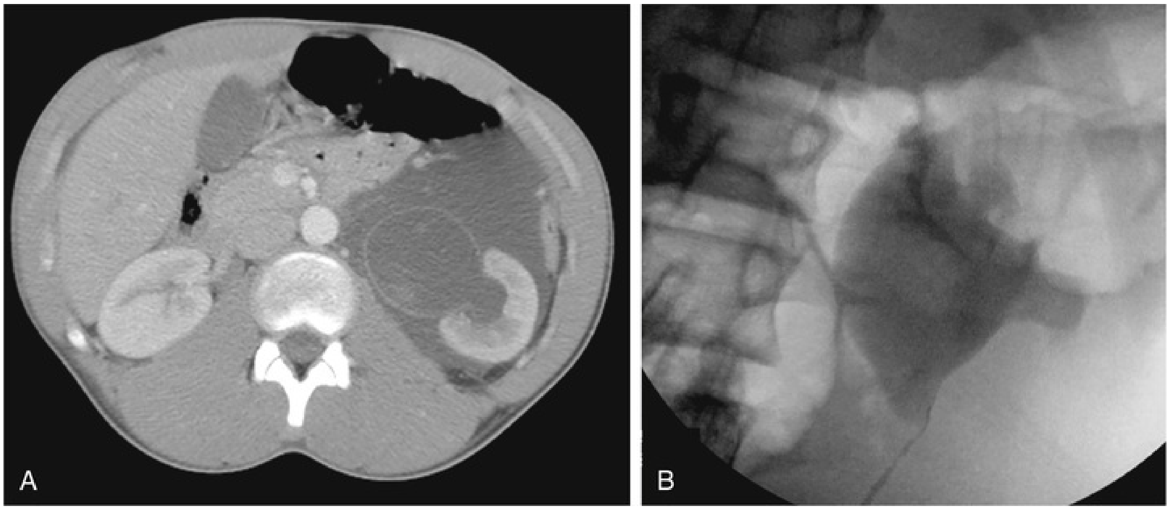

FIG. 52.8 Urine leak from renal pelvis laceration or rupture. Large fluid collection around dilated renal pelvis led to ureteral stent placement and percutaneous drain into urinoma (A). Percutaneous drain fluid consistent with urine and removed after drainage was minimal. Retrograde pyelogram at time of ureteral stent removal showing no extravasation (B).

Key Points: Operative Intervention Including Ureteropelvic Junction Disruption and Renal Pelvis Rupture

- Indications for operative intervention include hemodynamic instability caused by renal bleeding, pulsatile or expanding retroperitoneal hematoma at time of laparotomy without prior renal imaging, and failure of angioembolization to control renal bleeding.
- Control of renal vasculature should be performed immediately after opening Gerota fascia or before opening Gerota fascia.
- Operative intervention should include attempt to salvage the kidney if

possible.

- UPJ disruptions should be repaired in the acute phase if the patient is stable; otherwise drainage with a nephrostomy tube and possible percutaneous perirenal drainage with delayed repair should be performed.
- Renal pelvis rupture may require operative intervention but has been managed successfully with endoscopic and percutaneous urinary drainage.

Congenital Anomalies and Renal Injuries

Congenital anomalies such as duplex kidneys, fusion anomalies, hydronephrosis, hydroureter, and UPJ obstructions are occasionally seen at the time of renal injury (Onen et al., 2002). **In general, the risk for renal injury is not thought to be higher in patients with hydronephrosis or UPJ obstructions, but this is controversial** (Al-Qudah and Santucci, 2006; Chopra et al., 2002; McAleer et al., 2002; Schmidlin et al., 1998).

Ureteropelvic Junction Obstruction

A patient with a renal injury and UPJ obstruction can lead to interesting management decisions. **Although the most common injuries are still grade 1 to 2 renal injuries, urine leaks may require more aggressive management because of delayed drainage of urine through the UPJ.** A urine leak is most likely going to be a grade 4 injury through thinned renal parenchyma, but consideration for renal pelvis laceration or UPJ disruption should be given (Al-Qudah and Santucci, 2006; Ashebu et al., 2004; Chopra et al., 2002; Hall and Carpinito, 1994; Li et al., 2007; McAleer et al., 2002). If contrast is not seen in the ureter on excretory phase, retrograde pyelography should be performed to evaluate for UPJ disruption or renal pelvis laceration. UPJ disruption should be managed as described earlier. For patients with renal pelvic laceration and what appears to be a UPJ obstruction, we typically move quickly with ureteral stent placement and possible temporary perinephric drain placement. Nephrostomy tube placement with or without ureteral stent placement is also an option if the urine leak persists and exploration may be necessary (see Fig. 52.8). After the patient recovers from the injury, options include removal of the ureteral stent followed by pyeloplasty several weeks later or pyeloplasty with an indwelling ureteral stent. In our experience, removal of the ureteral stent followed by delayed robotic-assisted laparoscopic pyeloplasty 8 to 12 weeks later has worked well with minimal periureteral inflammation and scarring. However, given concern for infection in a poorly draining kidney after ureteral stent removal, a pyeloplasty with an indwelling ureteral stent in place can be performed.

Duplex Kidney

Duplication anomalies can make management of urine leaks more complicated, and urologists need to keep in mind that approximately 1% to 2% of the population have complete duplications of the renal collecting system, and partial duplications such as bifid pelvis are more common (Privett et al., 1976; Whitten and Wilcox, 2001). For example, if a ureteral stent is placed for a urine leak into the upper pole ureter when the urine leak is coming from the lower pole of the kidney, this obviously would not help the urine leak.

Fusion Anomalies and Ectopic Kidney

In general, renal injuries to kidneys with fusion anomalies or ectopic kidneys are managed similarly to kidneys without fusion or position anomalies. Horseshoe kidneys and ectopic kidneys are more likely to have hydronephrosis and UPJ obstructions and typically have anomalous vasculature, which may make management more complex (Gleason et al., 1994). Fig. 52.9 shows a case of horseshoe kidney with a grade 4 laceration to the left side with chronic UPJ obstruction that was managed with ureteral stenting and delayed pyeloplasty.

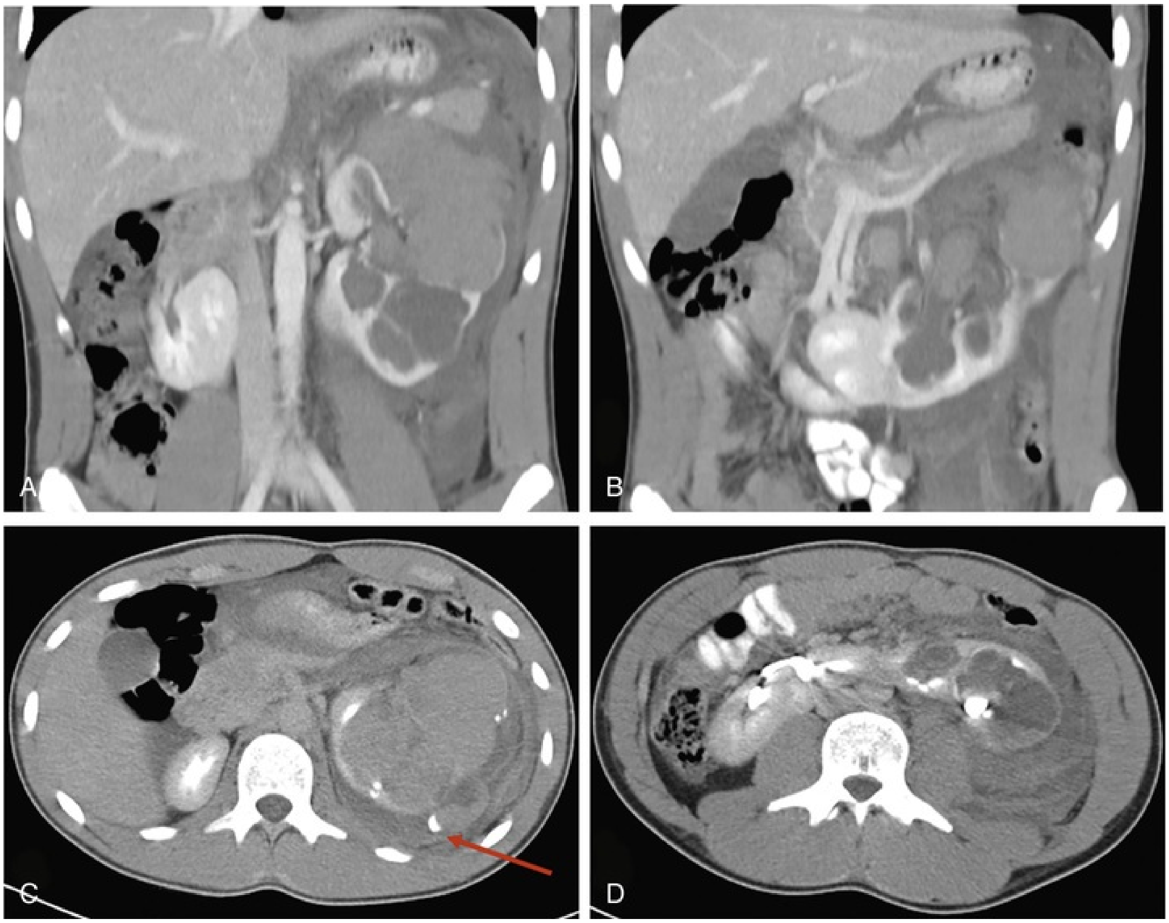

FIG. 52.9 Grade 4 injury to left-sided moiety with chronic ureteropelvic junction obstruction of a horseshoe kidney. Immediate contrast phases showing chronic-appearing hydronephrosis with hematoma in collecting system and perirenal hematoma (A and B). Delayed phases showing urine leak *(red arrow)* (C) and isthmus (D) of horseshoe kidney.

Follow-Up and Long-Term Issues

Once a patient has recovered from his or her traumatic injuries, several issues should be addressed with the patient and family. These issues include follow-up imaging, need for assessment of remaining renal function in the injured kidney, long-term risks of hypertension and chronic kidney disease, and physical activity limitations.

Late Repeat Imaging and Assessment of Renal Function

One issue that comes up at time of discharge is what follow-up imaging pediatric renal trauma patients should have. **The risk for renal scarring is likely negligible after a grade 1 to 2 injury, and repeat imaging is not recommended by the AUA urotrauma guidelines** (Dunfee et al., 2008; Morey et al., 2014; Surana et al., 1995)**. The risk for renal scarring is approximately 60% for grade 3 injures and closer to 100% for grade 4 to 5 injuries, with some decline in differential function** (Dunfee et al., 2008; El-Sherbiny et al., 2004; Tasian et al., 2010). Some have recommended a follow-up CT scan at 3 months in grade 3 to 5 injuries, and others have advocated for follow-up ultrasonography. DMSA or MAG3 renal scans can be obtained to evaluate renal function after recovery from injury, but it is unclear if they change management in the majority of cases. **Typically renal scans are obtained if there is concern about significant loss of function and/or if hypertension is present in follow-up.** Keeping with the ALARA concept, at our institution we obtain a renal ultrasonography 2 to 4 months after a grade 3 to 5 injury in children. If there is concern about significant loss of renal function, especially in the setting of hypertension, a DMSA scan would be discussed with the family. In patients with a very abnormal renal ultrasound scan or in those who underwent angioembolization, we would also consider a DMSA scan after discussing the option with family. **The EUA urogenital trauma guidelines recommend an individualized radiologic evaluation during follow-up for renal trauma** (Kitrey et al., 2018).

Hypertension

Hypertension that develops or persists 30 days after renal injury should raise the possibility of renal trauma–related hypertension. The risk for renal trauma–related hypertension is uncommon in grade 1 to 2 injuries. **In adults after a grade 3 or higher injury, the risk for developing hypertension is likely 5% to 15%** (Osterberg et al., 2018). Renal vascular hypertension is thought to arise from renal parenchymal ischemia leading to increased renin levels, renal parenchymal compression leading to increases in renin (Page type kidney), trauma-induced vascular anomaly such as arteriovenous fistula or pseudoaneurysm, or significant renal scarring from injury. Most pediatric series report between a 0% and 5% incidence of hypertension (LeeVan et al., 2016).

Evaluation of renal vascular hypertension typically includes nephrology referral, renal ultrasonography, assessment of function and scarring by renal scan, and evaluation for vascular malformation such as arteriovenous fistula by magnetic resonance imaging (MRI) or CT if there is a concern for this. Because the hypertension is thought to be mediated by elevated renin levels, angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) are often used to medically control the hypertension. In a patient with hypertension and a poorly functioning, scarred kidney after a grade 4 to 5 injury or one that required angioembolization, consideration for nephrectomy should be given in consultation with nephrology. **A Page type kidney in which a subcapsular fluid collection is compressing renal parenchyma leading to renin-mediated hypertension is rarely seen** (Moriarty et al., 1997; Sokhal et al., 2018). Drainage of the compressing hematoma/fluid collection or nephrectomy have been reported to be successful in resolving hypertension, but long-term outcomes are unclear (Moriarty et al., 1997; Sokhal et al., 2018).

Chronic Flank Pain

Chronic flank pain after renal injury is uncommon and is not addressed in pediatric series (Al-Qudah and Santucci, 2006; LeeVan et al., 2016). Evaluations may include urine analysis and urine culture, renal ultrasonography, CT, MRI, and renogram to exclude an obvious renal etiology for the pain such as nephrolithiasis or UPJ obstruction. Consideration for musculoskeletal causes of pain or other causes of flank pain should be given. We recommend pain management referral for evaluation for medical management or nerve blocks before considering nephrectomy, even in patients with a poorly functioning kidney, as flank pain may persist after nephrectomy.

Chronic Kidney Disease

The risk for chronic kidney disease is mainly a concern for parents of a child who either required a nephrectomy for renal injury, had bilateral renal injuries, or who had almost complete loss of function in one kidney because of renal injury. We inform families that hypertension and diabetes are the most common causes of chronic kidney disease in people with a solitary kidney and that healthy lifestyles should be promoted (Ibrahim et al., 2016). If there is concern for developing hypertension or diabetes in the future (e.g., a child with obesity), appropriate referrals are made. We recommend that families pay attention to yearly blood pressure evaluation for patients with a solitary kidney or a history of grade 3 to 5 renal injury. **The loss of a kidney resulting from renal trauma is thought to play a role in the development of end-stage renal disease in 0.5% of patients based on a review of the National Trauma Data Bank and other national datasets** (Dozier et al., 2013)**. In patients who have a solitary kidney from donation, there may be a slightly increased risk for hypertension, but it is unknown if this increases the risk for chronic kidney disease** (Boudville et al., 2006; Sanchez et al., 2018)**. We offer referral to a nephrologist if a family is concerned and wants yearly monitoring for a solitary kidney.**

Follow-Up and Activities With a Solitary Kidney

The risk for renal injury with organized sports is lower than from motor vehicle accidents, and the grades of injury are lower than what is seen in motorized sports activities, such as all-terrain vehicles or dirt bikes (Gerstenbluth et al., 2002; Wu and Gaines, 2007). However, renal injury from sports is more likely to be an isolated injury (Patel et al., 2015). **The American Association of Pediatrics states that children with normal solitary kidneys can participate with sports and should use flank protection if participating in contact sports such as hockey or football** (Rice and American Academy of Pediatrics Council on Sports Medicine and Fitness, 2008)**. Higher risk activities include dirt-bike riding, cycling, and riding all-terrain vehicles** (Brown et al., 2002; Gerstenbluth et al., 2002; Wu and Gaines, 2007). If the patient wants to participate in these activities, the patient and family need to be aware of the increased risk for renal injury and that protective equipment should be worn. We typically clear patients with a normal solitary kidney for participation in organized sports and recommend protective gear for contact sports. We remind families that contact sports such as football, rugby, and hockey are associated with a higher risk for head injuries (Pfister et al., 2016).

Key Points: Follow-Up and Long-Term Issues

- The risk for renal scarring is negligible in grade 1 to 2 injuries, approximately 50% in grade 3 injuries, and 100% in grade 4 to 5 injuries.
- Follow-up imaging for grade 3 to 5 injuries should be considered. Starting with renal ultrasonography and obtaining CT, MRI, or DMSA scans if

necessary is a common approach.

- Hypertension is a rare occurrence after renal trauma in children and typically is only seen after grade 3 to 5 injuries.
- The development of chronic kidney disease or end-stage renal disease is very rare after renal trauma, even when nephrectomy is performed.
- Patients with a normal solitary kidney can participate in sports, but protective equipment is recommended for contact sports. High-risk activities include dirt-bike riding, cycling, and all-terrain vehicle riding.

Ureteral Trauma

Epidemiology

Traumatic ureteral injuries are quite rare. In adult series, they occur in less than 5% of penetrating trauma cases and are very rare in blunt trauma cases (Marekovic et al., 1997; Medina et al., 1998; Paquette, 2007; Siram et al., 2010). **A ureteral injury should be considered as a possibility in patients with penetrating trauma near the ureter or with a trajectory toward the ureter, in patients with multivisceral abdominal injuries or vertebral injuries, and in patients with rapid deceleration injuries** (Elliott and McAninch, 2003; Siram et al., 2010). There is a high risk for associated kidney, vascular, bowel, and other solid organ injuries with penetrating trauma and a high risk for associated pelvic fracture with blunt trauma (Elliott and McAninch, 2003; Siram et al., 2010). **Because of the severity of associated injuries, there is a high mortality rate in patients who sustain a ureteral injury from trauma, reported to be around 10%** (Best et al., 2005; Siram et al., 2010). Renal injuries have been reported in about 20% of those with ureteral injury (Elliott and McAninch, 2003). Ureteral injuries are important to diagnose as a delayed or missed diagnosis is associated with increased likelihood of nephrectomy and prolonged hospital stay (Elliott and McAninch, 2003; Kunkle et al., 2006).

Ureteral injuries can occur during open or laparoscopic surgical procedures typically involving the rectum, colon, urologic structures, or gynecologic structures. Intraoperative injuries can include suture ligation, crush injury, partial or complete transection, devascularization, and injury from electrocautery. In addition, significant ureteral injuries can rarely occur during ureteroscopy (de la Rosette et al., 2014). The epidemiology of iatrogenic ureter injuries has been reported in adults with gynecologic or colorectal surgery (around 1%) having the highest incidence, but limited to case reports or small series in children (Goodno et al., 1995; Marcelissen et al., 2016; Park et al., 2012; Routh et al., 2009).

Presentation

As stated earlier, blunt trauma patients with ureteral injuries often have other injuries including pelvic fractures caused by high-velocity injuries. With penetrating trauma, the entrance is often near the area of the ureter or with a trajectory toward the ureter. In many cases, there is gross or microscopic hematuria, but a lack of hematuria is seen in around 25% to 50% of cases (Elliott and McAninch, 2003; Medina et al., 1998). The majority of patients with penetrating trauma will have traumatic ureteral injuries diagnosed intraoperatively (Best et al., 2005; Elliott and McAninch, 2003). **Even with laparotomy at the time of injury, around 10% of ureteral injuries will be missed at laparotomy and have a delayed diagnosis** (Kunkle et al., 2006)**.**

High-velocity (>610 m/sec) gunshot wounds can cause tissue injury well beyond the path of the projectile. In addition, the projectile can tumble or have significant course changes that will result in damage to organs. Examples of high-velocity guns include military assault rifles and AR-15–style rifles. In cases of high-velocity gunshot wounds, it has been reported that at the time of initial laparotomy the renal pelvis, ureter, and bladder may appear uninjured or slightly contused only to develop necrosis several days later with urine extravasation (al-Ali and Haddad, 1996; Cetti, 1983; Stutzman, 1977). **Ureteral stent and drain placement around urinary structures is recommended after laparotomy for high-velocity gunshot wounds if there is any suspicion of a urine leak developing so the leak can be readily identified and managed.**

In cases of intraoperative ureteral injury, this can be identified immediately, but diagnosis can be delayed in 50% to 60% of patients until they present with urine output from surgical drain, urinary ascites, ileus, fever, or sepsis (Blackwell et al., 2018).

Imaging Findings

A delayed-contrast phase of CT is typically the imaging study used to diagnose ureteral injury and is recommended by the AUA urotrauma guidelines (Morey et al., 2014). Findings will include lack of contrast in the ureter distal to the injury with extravasation in complete ureteral transections or possibly some contrast in the ureter distal to the injury with extravasation in partial ureteral injuries. Other imaging studies that can be used to confirm or diagnose ureteral injury include retrograde pyelography or IVP.

American Association for the Surgery of Trauma Classification

The AAST OIS classification for ureteral injury is shown in Table 52.4 and correlated with complexity of repair and associated injuries by one study (Best et al., 2005; Moore et al., 1992). Grade 1 injuries may not require any intervention. Grade 2 to 3 injuries will require at least an endoscopic intervention and potentially an open or laparoscopic repair. Grade 4 to 5 injuries will require an open or laparoscopic repair either at time of diagnosis or in a delayed fashion. The management of complete and partial transections is also affected by location of injury as discussed in the following sections.

TABLE 52.4

Ureteral Injury: American Association for the Surgery of Trauma Organ Injury Scale

Contusion or hematoma without devascularization
<50% transection
>50% transection
Complete transection with <2 cm devascularization
Avulsion with >2 cm devascularization

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

Management of Traumatic Ureteral Injury

Immediate Diagnosis

Penetrating or blunt trauma, if a partial or complete ureteral transection injury is diagnosed intraoperatively and the patient is stable, should be repaired intraoperatively under the same anesthetic (Kitrey et al., 2018; Morey et al., 2014). Intraoperative injuries should be repaired under the same anesthetic if diagnosed at that time. The type of repair used depends on length of ureteral injury and location. For ureteral contusions, ureteral stent or excision with repair can be performed depending on the clinical scenario (Kitrey et al., 2018; Morey et al., 2014).

If a trauma patient is unstable, urinary diversion with delayed repair may be necessary (Kitrey et al., 2018; Morey et al., 2014). In these damage-control situations, the ureter can be tied off followed by nephrostomy tube placement, the ureter can be brought to the skin, a ureteral stent can be placed and brought to the skin, or, if there is no time, a large drain can be left near the ureteral injury.

Delayed Diagnosis

For ureteral injuries diagnosed within the first week of injury, immediate surgical repair is an option (Morey et al., 2014). If a ureteral injury diagnosis is delayed more than 5 to 7 days after injury, classically these patients have been managed with urinary diversion with nephrostomy tube and possible drain or ureteral stent with planned delayed repair. The optimal length of time one should wait until delayed repair is unknown, but recommendations between 6 and 12 weeks are common. Some authors have challenged this idea and recommend an attempt at placement of a ureteral stent. If a ureteral stent can be placed across the injury, authors have reported ureteral injuries including partial and complete ureteral transections healed without the need for open intervention from 15% to 75% (Chung et al., 2017; Koukouras et al., 2010; Liatsikos et al., 2006; Liu et al., 2014; Morrow et al., 2017). The AUA guidelines recommend attempts at ureteral stent placement for partial ureteral injuries that are diagnosed in a delayed fashion, but this has been reported as an option for complete transections as well (Liu et al., 2014; Morey et al., 2014). The EAU urogenital trauma guidelines state that endourologic management is the initial approach in most cases of delayed diagnosis of ureteral injury, and open repair is needed in failures (Kitrey et al., 2018).

Proximal or Mid-Ureteral Injury Surgical Repair

A very proximal ureteral injury can be managed similar to a UPJ disruption (see the Ureteropelvic Junction Disruption section earlier in this chapter) with a tension free spatulated anastomosis of ureter to renal pelvis. A partial transection of the mid- to upper- ureter can be repaired surgically either by ureteroureterostomy with a spatulated, tension-free anastomosis or closure of the partial transection without narrowing the ureteral lumen. A transureteroureterostomy may be less desirable in children given longer life span and potentially putting the other kidney at risk. A Boari flap can reach the mid- to proximal ureter if the distal ureter is not available. Typically, a ureteral stent is left in place for 4 to 6 weeks, but the optimal duration is unknown. Series specific to the pediatric population are limited, but favorable outcomes have been reported in mid- to proximal ureteral injuries (Routh et al., 2009).

Distal Ureteral Injury Surgical Repair

There are several options for surgical repair of distal ureteral injuries. Ureteroureterostomy and ureteral reimplant with or without psoas hitch with ureteral stenting are used for most repairs. Series in the pediatric population are limited, but results indicate favorable outcomes with these methods (Routh et al., 2009).

Lengthy Ureteral Injuries

Lengthy ureteral injuries are thankfully very rare. **Options to restore drainage of the kidney to the bladder include long Boari flap, ileal ureter, and autotransplantation** (Brandes and McAninch, 1999; Kastelan et al., 2004; Sevinc et al., 2016). The management of these cases is highly individualized. Nephrectomy is also an option, especially for a poorly functioning kidney with a normal contralateral kidney.

Follow-Up Imaging

Follow-up imaging after any ureteral injury is recommended. Once the ureteral stent is removed, renal ultrasonography is obtained in 4 to 6 weeks. If there is no hydronephrosis, we recommend at least yearly ultrasound examinations for 2 to 3 years. If there is any concerning hydronephrosis with or without flank pain, a MAG3 diuretic renogram can be obtained to assess function and drainage. If there is concern for postinjury ureteral stricture, antegrade and retrograde pyelography is helpful in determining length and location. If a postinjury ureteral stricture occurs, some advocate for endoscopic management with dilation or incision of the stricture, but a significant minority will have recurrent strictures (Erdogru et al., 2005; Richter et al., 2000; Seseke et al., 2002).

Key Points: Ureteral Injuries

- Ureteral injuries are rare in any trauma but are more commonly seen with penetrating trauma.
- Contrast-enhanced CT with delayed phase or retrograde pyelography are the preferred methods used to diagnose a ureteral injury.
- Ureteral injuries are often associated with other organ injuries in trauma cases, and ureteral injuries can be missed at initial laparotomy for trauma.
- If a ureteral injury is diagnosed less than 1 week from injury, immediate repair can be performed and may be preferable if the patient is stable.
- If a ureteral injury is diagnosed more than 1 week from injury, an attempt at ureteral stent placement can be made, but often a nephrostomy tube with delayed open repair is needed.
- Ureteral injuries in children are repaired similar to adults.

Bladder Injuries

Presentation

Although injuries such as gunshot wounds and other penetrating injury do occur in the pediatric bladder, this is less common than seen in the adult population. **In children, the mechanism for injury to the bladder and urethra is blunt trauma in more than 80% of cases** (Deibert et al., 2012). Isolated bladder trauma is rare in children; however it is more common than in the adult population. This is possibly due, in part, to the fact that more of the bladder is intraperitoneal in children (Brereton et al., 1980). **Severity scoring mirrors that used in adults are shown in Table 52.5, and the critical differentiation is whether the injury is intraperitoneal or extraperitoneal, as in the adult population.**

TABLE 52.5

Bladder Injury: American Association for the Surgery of Trauma Organ Injury Scale

Contusion, intramural hematoma, or partial-thickness laceration
Extraperitoneal bladder wall laceration <2 cm
Extraperitoneal (>2 cm) or intraperitoneal (<2 cm) bladder wall laceration
Intraperitoneal bladder wall laceration >2 cm
Intraperitoneal or extraperitoneal bladder wall laceration extending into the bladder neck or ureteral orifice (trigone)

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

Pelvic Fracture

In a review of the National Trauma Data Bank from 2002 to 2008, Deibert et al. reported on 816 children that were found to have bladder trauma (Deibert et al., 2012). Most of these patients were also noted to have a pelvic fracture, which was the likely cause. As expected, the injury is typically found because of hematuria or because the mechanism of injury prompts a study to rule out involvement of the urinary tract.

Pelvic fractures occur less commonly in children and are associated with more severe intra-abdominal injuries. In fact, children may be only one-half as likely to have a pelvic fracture. This is likely because the bony pelvis in a child is more pliable, and therefore more force is required to generate a fracture (Chia et al., 2004; Demetriades et al., 2003). Because of this, it has been hypothesized that this may lead to more severe intra-abdominal injuries in children when a pelvic fracture has occurred, but this is not always borne out in the literature (Demetriades et al., 2003). **About one-half of children with a bladder injury might be expected to have a pelvic fracture** (Sivit et al., 1995), demonstrating that even without a bony pelvis injury the bladder is still at risk in the pediatric patient. In addition, injuries to the bony pelvis in smaller children differ from those in adolescents and adults, which also may play a role in differing patterns of injury to surrounding pelvic organs. These changes probably occur during the early teenage years (Silber and Flynn, 2002).

Imaging

In determining the need to obtain radiographic or cystoscopic evaluation in the presence of pelvic trauma, the presence of gross hematuria or urinary retention is paramount. According to the AUA urotrauma and EAU urogenital trauma guidelines, evaluation for a bladder injury with cystography (either plain radiography or CT) should be done in patients with pelvic fracture and gross hematuria, in patients with gross hematuria and mechanism concerning for bladder injury, and in patients with pelvic fracture and clinical signs of bladder rupture (Kitrey et al., 2018; Morey et al., 2014).

The presence of hematuria in the trauma patient warrants radiographic workup for injury to the upper urinary tract as described earlier, however a retrograde contrast-based study (CT or standard cystography) is recommended to evaluate the lower urinary tract when there is concern for possible bladder or urethral injury. This is particularly true in the case of hematuria with concomitant pelvic fractures, given that about one-half of these patients will be found to have a bladder rupture (Hochberg and Stone, 1993). Delayed imaging on CT is critical to evaluate renal and ureteral injury but may not be sensitive enough to elucidate bladder involvement (Haas et al., 1999). Cystography can also obviate the need for intravenous contrast if a catheter is in place or can be placed. A retrograde urethrogram can be obtained at the same time if there is concern for urethral injury as described later.

Management

The management of isolated bladder injury depends largely on the location of the injury. Injuries in the pediatric population can be categorized by intraperitoneal and extraperitoneal location in addition to bladder neck injuries as in the adult population. These distinctions largely dictate the type of intervention. As in adults, extraperitoneal injury can be managed without repair in most cases. Exceptions arise when there is concern for boney fragments protruding into the bladder that are exposed to urine, thus raising the risk for complex infections in the bony pelvis. In addition, if an orthopedic procedure requires hardware in the pelvis, closure is necessary to prevent seeding of the hardware with infected urine. **AUA and EAU guidelines give intraperitoneal location of a bladder injury as an absolute indication for surgical repair along with extraperitoneal location that involves exposed bone, concomitant rectal or vaginal laceration, or need for internal fixation or abdominal** surgery (Kitrey et al., 2018; Morey et al., 2014).

Closure of an extraperitoneal bladder injury is typically performed at the time of other operative intervention such as orthopedic fixation of the pelvis. This can be done through a midline incision, particularly if a laparotomy needs to be performed for evaluation and treatment of intra-abdominal solid organ injury. We perform a two-layer closure with running absorbable suture. A Foley catheter is left for 1 to 2 weeks, and a drain can be left in the perivesical space at the surgeon's discretion. A cystogram is obtained at the time of catheter removal.

Injury to the bladder neck is more common in children and can be particularly difficult to manage (Boone et al., 1992; Husmann et al., 1990; Koraitim, 2015). If a tear extends through the bladder neck, a formal repair is necessary. The outcome of the repair may depend on the severity of the injury with complete avulsion having poorer rates of postrepair continence, particularly in female patients who likely depend more on the bladder neck mechanism for continence than male patients (Black et al., 2006). **Regardless, urinary continence in this group of injuries is notoriously poor, with many requiring secondary**

procedures and even bladder neck closure and diversion to achieve complete dryness (Routh and Husmann, 2007).

Although an extraperitoneal bladder rupture can often be observed, intraperitoneal ones are repaired as a rule because of the potential for an uncontained peritoneal urinoma and associated morbidity and even mortality. There is evidence that a select group of intraperitoneal ruptures can be managed without operative intervention, but this is controversial. If observed, the patient with an intraperitoneal injury requires continuous drainage of the bladder and potential abdominal urinoma, raising the question of whether a repair of the defect is less morbid (Osman et al., 2005). Therefore, intraperitoneal injuries are typically managed by laparotomy either at the time of exploration of concomitant injury or on their own. A catheter is typically left in place for approximately 1 to 2 weeks depending on the nature of the trauma and is removed with follow-up cystography.

Urethral Injuries

Categorization of urethral injury in children parallels the adult system of posterior and anterior injuries and adult severity scoring (Table 52.6). In addition, the Goldman classification is frequently used because of its clinical utility (Table 52.7) (Goldman et al., 1997). Posterior injuries, including those that incorporate the bladder neck, occur most frequently with straddle injury and pelvic fracture as in adults (Helmy et al., 2014). As described earlier, the differences in occurrence lie in the fact that pelvic fracture in children requires a higher energy mechanism so that when there is a pelvic fracture, the likelihood of concomitant injury of surrounding structures such as the urethra is substantially higher (Delaney et al., 2016). In addition, children are more likely to have injuries of the supraprostatic and prostatic urethra itself than adult men who more often have injuries at the bulbomembranous junction (Boone et al., 1992; Onen et al., 2002). Injuries of the anterior urethra including those of the pendulous urethra are described later in the Penile Injury section.

TABLE 52.6

Urethral Injury: American Association for the Surgery of Trauma Organ Injury Scale

Blood at urethral meatus; retrograde urethrography normal (contusion)

Elongation of urethra without extravasation on urethrography (stretch injury)
Extravasation of urethrography contrast at injury site with visualization in the bladder (partial disruption)
Extravasation of urethrography contrast at injury site without visualization in the bladder; <2 cm of urethral separation (complete disruption)
Complete transaction with >2 cm urethral separation or extension into the prostate or vagina (complete disruption)

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

TABLE 52.7

Urethral Injury: Goldman Classification for Blunt Urethral Trauma

Posterior urethra stretched but intact
Urethral rupture above intact urogenital diaphragm
Injury extends through the urogenital diaphragm; involves proximal bulbous urethra
Extraperitoneal bladder rupture with extension into proximal urethra
Anterior urethral injury

Modified from Goldman SM, Sandler CM, Corriere JN Jr, McGuire EJ. Blunt urethral trauma: a unified, anatomical mechanical classification. *J Urol*. 1997;157(1):85–89.

Evaluation

Urethrography should be performed when the mechanism of injury is concerning for pelvic trauma (e.g., straddle injury, motor vehicle accident with pelvic fracture). Typically a history of urinary retention or gross hematuria is elicited. Examination findings such as blood per urethra or from the vagina and perineal hematoma are also concerning for urethral injury and should prompt radiographic and/or cystoscopic workup. Oftentimes, by the time the urologist is at the bedside, other imaging in the form of a CT scan or plain radiograph has been obtained and can be used to confirm or rule out the presence of concomitant pelvic bony or organ injury. **AUA urotrauma guidelines advise retrograde urethrography in all cases with blood at the meatus in the setting of pelvic trauma** (Morey et al., 2014).

Management

The severity of the urethral defect plays a large role in how the treatment is addressed at the outset. If a catheter has not already been placed, we favor retrograde urethrography before attempted placement when there is concern for injury. Although this can be more difficult in children, particularly when awake, it is critical in evaluating the extent of injury, particularly to determine whether there is a complete versus partial disruption of the urethra. If a catheter has already been placed, retrograde urethrography can be performed around the catheter or voiding cystourethrography can be performed if the patient can void with the catheter in place. Ultimately, an examination under anesthesia with cystourethroscopy may be necessary if other studies are inconclusive.

If a catheter has been placed before evaluation, this suggests that the injury is not likely to be a complete disruption. This can be confirmed by retrograde urethrography as described earlier. In these cases, it is recommended to manage the injury with catheter drainage and reassess in several weeks. Although resultant strictures can be treated endoscopically with urethrotomy, about one-half of these recur, and repeated attempts at endoscopic management should be avoided (Hsiao et al., 2003).

When unable to achieve urethral drainage in the acute setting, a suprapubic tube must be placed. Initial management options for the urethra include an attempt at primary realignment performed under cystoscopic and fluoroscopic guidance, open primary realignment, and delayed repair in several weeks to months. In children, when there has been complete disruption of the urethra or avulsion from the bladder, there is some evidence to suggest that primary realignment performed endoscopically can have good results (Herschorn et al., 1992; Onen et al., 2005a, 2005b). Others advocate against this because of high rates of stricture and subsequent need for further intervention (Husmann et al., 1990). However, primary alignment may not be advisable for several reasons. In the case of endoscopic alignment, it may simply be too difficult to identify the bladder neck and access the bladder. In the attempt to do so, irrigation is infused into the pelvis, potentially complicating a simple hematoma and expanding the space between the bladder and the pelvic floor. It is also argued that prior endoscopic attempts at realignment can negatively impact the success of a delayed open repair when necessary (Culty and Boccon-Gibod, 2007; Singh et al., 2010). Therefore, in the stable patient an attempt can be made to pass a catheter endoscopically, but prolonged attempts should be avoided.

Open realignment in the acute setting often requires further endoscopic treatment or open revision making the benefit of attempting this questionable (Nerli et al., 2008). In addition, once the pelvic space is violated, a hematoma, once controlled by tamponade, may no longer be contained and is free to bleed. A once-stable patient with a contained pelvic bleed can rapidly deteriorate. Poor visualization in the operative field may also lead to excessive debridement, which may be why erectile dysfunction and incontinence rates have been shown to be higher when immediate open repair is attempted (Brandes, 2006; Koraitim, 1996). **These considerations led the EUA to recommend against attempts at immediate urethroplasty** (Kitrey et al., 2018). This is despite the findings by some that the results can be quite similar to delayed repair (Husmann et al., 1990). One more clear indication for immediate repair is with an associated bladder neck injury. It has been shown to be beneficial to repair the injury up-front largely as a result of concern for resultant urinoma and infection rather than long-term benefit of the early repair (Routh and Husmann, 2007).

If a catheter cannot be placed easily, a suprapubic catheter can be left in place and allowed to drain until a repair can be performed at a later date (Trachta et al., 2016). For a delayed urethral repair, we typically wait several months from the date of injury to let the scar mature. If there is a pelvic hematoma that has elevated the bladder up off the pelvic floor, common in the case of a complete urethral disruption, it will resolve over this period, allowing the bladder to descend back into the pelvis, facilitating the repair. This evolution of the scar can change a defect that appeared rather large in the acute setting into a relatively small one later on**. For this reason, it is recommended to reevaluate any patient needing a delayed formal repair with imaging and cystourethroscopy closer to the date of the repair.** In these cases, a suprapubic catheter was inevitably placed at the time of the initial presentation. This access helps in determining the size of the gap between bladder neck and patent urethra. This can be easily assessed by cystography and retrograde urethrography or a combination of radiologic imaging with cystoscopy from below and/or above through the suprapubic cystotomy site. Fig. 52.10 shows an example of pelvic fracture with urethral disruption injury.

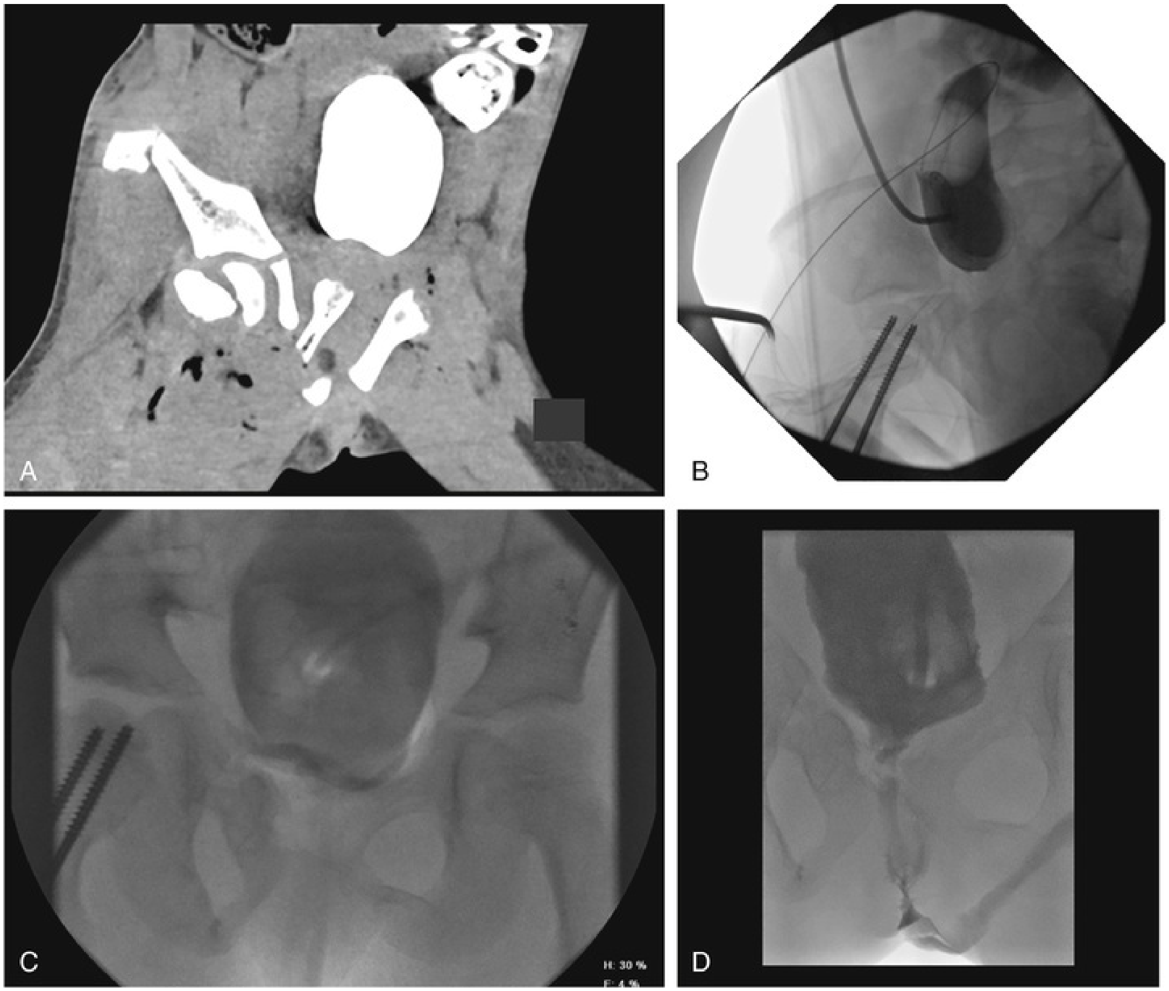

FIG. 52.10 Pelvic fracture with urethral disruption injury in a 6-year-old female patient. CT scan at presentation and initial cystogram demonstrating elevation of bladder off of shattered pelvis (A and B). Cystogram after resolution of hematoma with descent of bladder back into pelvis before reconstruction (C). Voiding cystourethrogram after reconstruction (D).

In children, even with the most severe injuries, excision of the scar with primary anastomosis is typically feasible to perform without concern about tension on the anastomosis (Helmy et al., 2014). We perform this through a perineal approach with the child in the lithotomy position, making sure to prepare the lower abdomen in case the bladder needs to be mobilized from above. A midline incision is made on the perineum, and the urethra is mobilized and circumscribed. This can be dissected distally to the glans if necessary. Proximal dissection is performed to the scar and, assuming a primary repair is being performed, the urethra is transected through the scar. The bladder neck can be difficult to identify depending on the extent of the scar. This is facilitated by the passage of a sound through the suprapubic site into the bladder neck. An incision through the scar onto the sound then provides a more direct entry into the bladder neck. The scar is then excised aggressively from both the distal and proximal portions of the urethra until only soft tissue with good blood supply is present. The urethra is then spatulated and the anastomosis is performed with interrupted dissolving suture over a Foley catheter. If there is tension on the anastomosis after mobilization of the urethra, more length can be obtained first by partial pubectomy and then by mobilization of the bladder from above through an abdominal incision. The catheter is left in place for approximately 2 to 3 weeks. The suprapubic tube is removed after a voiding trial and cystogram. A similar technique can also be performed through a posterior sagittal transanorectal approach (Onofre et al., 2011).

If the gap is too large for excision and primary anastomosis, several options are available for reconstruction. Skin or buccal inlays can be used as grafts or flaps. Interposition with appendix, bowel, and ureter has also been described for larger defects. Defects less than 5 cm in length, however, are typically amenable to excision and primary anastomosis. This is the case in almost all initial repairs, however in the situation of reoperation, the defects can be longer (Aggarwal et al., 2002; Sunay et al., 2011).

Postoperative outcomes in children are generally favorable. Complications can include urinary retention (either caused by atony or recurrent stricture), incontinence, penile shortening, and erectile dysfunction as in adults, however the rates are lower (Trachta et al., 2016). **AUA urotrauma guidelines recommend that follow-up be continued for at least 1 year after the repair** (Morey et al., 2014).

Recurrent stricture occurs in about 10% of pediatric patients, at which point internal urethrotomy can be attempted, although failure rates are high. As expected, this is more successful with shorter (<1 cm) postoperative strictures, and a repeat urethroplasty may be necessary if it fails (Aggarwal et al., 2002; El-Sheikh et al., 2008; Helmy et al., 2014; Onofre et al., 2011). Redo urethroplasty is understandably more likely to result in recurrent stricture due in part to the more complicated original lesion (Aggarwal et al., 2002).

Urinary incontinence can occur in as many as 20% of children and appears to relate to the type and extent of injury. It is more commonly associated with more proximal injuries such as those to the bladder neck or prostatic urethra (Boone et al., 1992; Onofre et al., 2011; Podesta and Podesta, 2015). In the case of urethral injuries that extend up into the bladder neck, continence rates are notoriously unfavorable regardless of the timing or type of repair (Routh and Husmann, 2007).

Postoperative erectile dysfunction seems to correlate with preoperative dysfunction with potential long-term recovery (Aggarwal et al., 2002; Podesta and Podesta, 2015). In addition, certain characteristics of the injury such as the severity of the fracture and length of the defect) can predict greater likelihood of dysfunction (Hemal et al., 2000; Husmann et al., 1990). This can occur in up to one-half of children and appears to occur more commonly in patients treated with acute open realignment, possibly providing a rationale to avoid attempts at immediate realignment (Boone et al., 1992; Koraitim, 2014). Other associated findings in patients with resultant erectile dysfunction are lateral prostatic displacement at time of injury and urethral gap larger than 2.5 cm (Koraitim, 2014).

Urethral Disruption in Females

Female urethral injury requiring intervention is rare. This happens almost exclusively in the presence of pelvic fracture and most often presents as a complete disruption below the bladder neck. The overall incidence of urethral injury in female pelvic fracture is about 5% (Black et al., 2006; Hosseini et al., 2009; Podesta and Jordan, 2001) but should be ruled out when hematuria, urinary retention, or injury to the vagina or rectum is present (Hemal et al., 2000; Perry and Husmann, 1992; Venn et al., 1999). Common etiologies include crush injuries, motor vehicle accidents, and falls involving pelvic fracture. As described earlier, management relies on suprapubic drainage initially with delayed repair several months after the trauma. Because the external sphincter is typically preserved, the reconstruction is performed as an excision of the scar with primary anastomosis. We perform this with the patient in the lithotomy position as we do in male patients, with the abdomen prepared in case bladder mobilization is necessary. Published continence results are favorable when the bladder neck is not involved (Hosseini et al., 2009; Podesta and Jordan, 2001), however incontinence, recurrent stricture, and fistula do occur (Hemal et al., 2000; Huang et al., 2003; Venn et al., 1999).

Key Points: Bladder and Urethral Injury

- A history of pelvic trauma with gross hematuria or inability to void and pelvic fracture necessitate urologic evaluation with retrograde urethrography and/or cystography.
- Indications to repair an extraperitoneal bladder rupture include need for placement of orthopedic hardware in the field, bony pelvis fragments protruding into the bladder, involvement of the bladder neck in the injury, and concurrent abdominal surgery.
- Intraperitoneal bladder ruptures are managed with surgical repair.
- Bladder neck injuries are more common in children and best served with early repair.

Genital Injury in the Pediatric Population

Although most genital injuries in children are accidental, it is critical to assess whether trauma to the penis or scrotum in boys, or the vagina in girls, is the result of abuse. About 1 in 7 boys and 1 in 3 girls will be sexually abused in childhood. In most of these cases, the abuse is penetrative (Briere and Elliott, 2003). This is not always obvious, and if there is any suspicion, ancillary services such as social services can be helpful in determining the safety of the child in his or her home environment on discharge from the hospital. In addition, when abuse is suspected, it is imperative to ensure that no other harm has been done. Often concomitant injuries go unnoticed, particularly to the anus and rectum.

Penile Injury

In larger series, most penile injury in children happens inadvertently from a number of causes. These include circumcision, hair tourniquet strangulation, motor vehicle accidents, animal bites, zippers, and burns or scalds, with circumcision making up the majority of the injuries. (El-Bahnasawy et al., 2002). Severity and type of injury directs evaluation and treatment (Table 52.8).

TABLE 52.8

Penile Injury: American Association for the Surgery of Trauma Organ Injury Scale

Cutaneous laceration/contusion
Buck fascia (cavernosum) laceration without tissue loss
Cutaneous avulsion, laceration through the glans/meatus, or cavernosal/urethral defect <2 cm
Partial penectomy or cavernosal/urethral defect >2 cm
Total penectomy

Modified from Goldman SM, Sandler CM, Corriere JN Jr, McGuire EJ. Blunt urethral trauma: a unified, anatomical mechanical classification. *J Urol.* 1997;157(1):85–89.

Amputation of the penis can occur with circumcision and strangulation injury, such as with a hair tourniquet. Depending on the technique and the training of the practitioner, newborn circumcision has been shown to have variable rates of complication and injury (Ceylan et al., 2007; Okeke et al., 2006). Minor injury involves the removal of excess skin, and severe injuries of partial or complete amputation of the glans penis can occur. **Typically these more profound injuries occur when performed without appropriate training. Injuries are less common in the hospital and clinic settings and are more often seen when a Mogen-type device is utilized.** This can be attributed to the lack of protective bell for the glans penis. Careful lysis of preputial adhesions can probably prevent the vast majority of these complications, even with use of a Mogen clamp (Pippi Salle et al., 2013). Hair or thread strangulation results in partial or circumferential damage with urethral injury or even penile loss. The damage is typically slow in onset and may not cause significant pain. In addition, the offending hair or thread may be too small to see. All of these factors can lead to late recognition and potentially greater harm (El-Bahnasawy et al., 2002).

When amputation occurs, whether caused by a complication of circumcision or caused by strangulation injury, careful repair often results in a good cosmetic outcome. This is the case with or without attempt at microvascular reanastomosis of the glans penis or penile shaft. A catheter is left in place for 1 to 2 weeks when a urethral anastomosis is used in the repair of the amputation. With a hair tourniquet injury, the injury may be less severe and can be managed conservatively. When surgical repair is necessary, outcomes have been favorable (Badawy et al., 2010).

Fistulae can also result from causes such as hair tourniquet strangulation or circumcision. Often a fistula caused by a hair tourniquet is on the proximal shaft. In these cases, a multilayer closure is usually performed if the fistula does not heal with an attempt at conservative management with catheter drainage. The outcomes for repair are quite favorable with occasional resultant urethral stricture or recurrent/persistent fistula (Badawy et al., 2010). In contrast, fistula from circumcision is often in a subcoronal position and may require splitting the glans and treating the injury in the manner of a hypospadias repair (Baskin et al., 1997).

Although blunt trauma to the penis in children is rare, Glass et al. reported relatively high numbers of patients presenting to emergency departments in the

United States with toilet seat crush injuries, with more than 9000 occurring from 2002 to 2010, reported through a consumer database (Glass et al., 2013). Usually this occurs in toilet training boys and most of these injuries are minor, typically managed conservatively and treated as an outpatient.

Burns to the genitalia are rare in children but occur more commonly than in the adult population. Most of these are caused by scalds. They are usually not isolated to the genitalia and can result in significant skin loss (Abel et al., 2012). This may require transposition of skin by either graft or flap technique. In our practice, we typically harvest from sites expected to bear less hair in the postpubertal male. We use full-thickness and unmeshed grafts to cover the penile shaft. This provides more natural-looking skin that moves more freely over the underlying corporal bodies. A bolster dressing is left in place for 5 to 7 days, and activity is limited. Excessive skin removal at the time of circumcision, however, can typically be managed conservatively with dressing changes, allowing the wound to heal by secondary intention with good cosmetic outcomes (Banihani et al., 2014; El-Bahnasawy et al., 2002).

In the case of animal bites, debridement and copious irrigation must accompany any treatment. If there is no obvious sign of infection, wounds can be reapproximated, usually, however, they are best left to heal by secondary intention (Gomes et al., 2001).

Scrotal Injury

Epidemiology

Testis trauma in children is rare. Of all surgical cases for acute scrotum, these make up less than 5% of trips to the operating room (Pogorelic et al., 2016). Penetrating trauma to the scrotum can include superficial injury to the skin and dartos or deeper injury into the tunica vaginalis (Table 52.9). Blunt trauma to the testis ranges from minor hematoma to testicular rupture, with extrusion of seminiferous tubules as described by the AAST severity scoring for testicular trauma shown in Table 52.10.

TABLE 52.9

Scrotal Injury: American Association for the Surgery of Trauma Organ Injury Scale

Contusion

Laceration <25% of scrotal diameter
Laceration >25% of scrotal diameter
Avulsion <50%
Avulsion >50%

TABLE 52.10

Testicular Injury: American Association for the Surgery of Trauma Organ Injury Scale

Contusion/hematoma
Subclinical laceration of tunica albuginea
Laceration of tunica albuginea with <50% parenchymal loss
Major laceration of tunica albuginea with >50% parenchymal loss
Total testicular destruction or avulsion

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

Imaging

As with suspicion for testicular torsion, often a good history or examination warrants immediate operative intervention, and no imaging is necessary. However, for a child with scrotal trauma, scrotal imaging in the form of ultrasonography can be helpful in determining whether there is a rupture of the testis. **Ultrasonographic signs of rupture include discontinuity of the tunica albuginea, hematocele, and loss of Doppler signal to part of or the entire testis.** Fig. 52.11 shows an example of testis rupture case.

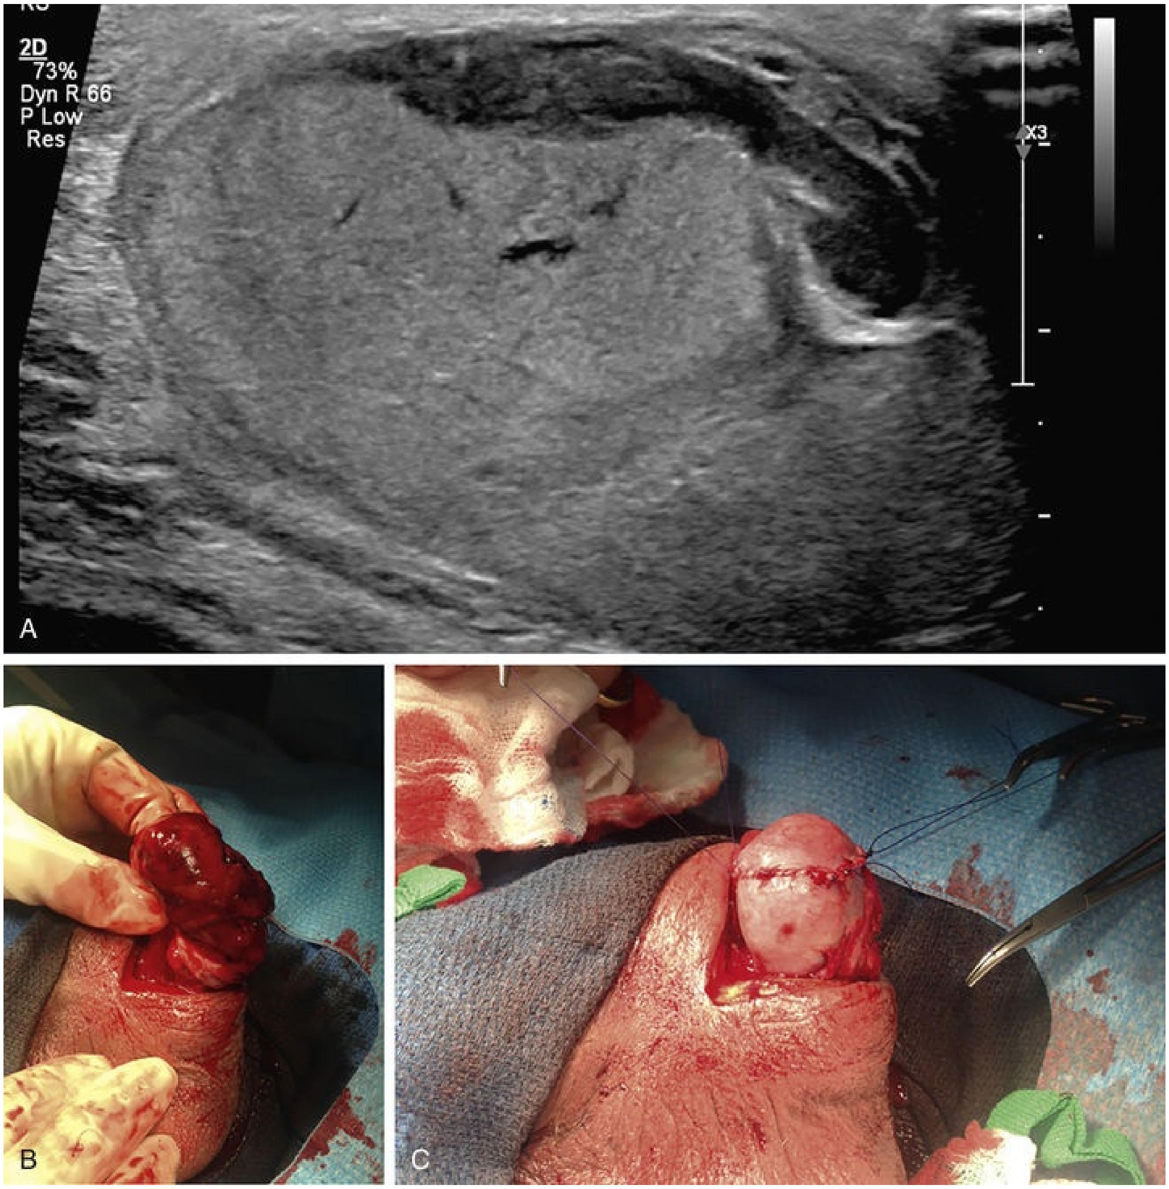

FIG. 52.11 Testis rupture with preoperative ultrasound (A) and intraoperative images before and after repair (B and C).

Management

As in adults, penetrating scrotal lacerations can be managed simply with washout and closure given that the tunica vaginalis is not violated. In children, this can often be performed in the emergency department with local anesthetic and minimal sedation if any. If there is concern about entry into the tunica vaginalis or if there is extrusion of the testicle, a more formal debridement and washout in the operating room is indicated. Depending on the nature of the injury, a drain might be left for several days.

Management of blunt trauma to the scrotum is dependent on whether there is a concern about testicular rupture. In the case in which the tunica albuginea does not appear intact on the ultrasonography or there is an apparent hematocele, testicular rupture is suspected, and exploration is typically recommended.. **In the case of rupture, most literature advocates for debridement and repair of the tunica albuginea in the operating room in the acute setting, and this is supported by AUA urotrauma and EAU urogenital trauma guidelines** (Kitrey et al., 2018; Morey et al., 2014). Some authors, however, have advocated for conservative management even when a rupture is confirmed. In a recent series, atrophy rates in this setting were less than 20% (Redmond et al., 2018).

Loss of scrotal skin often can be managed by coverage with surrounding skin with an advancement flap. This is the case, even with significant skin loss after scrotal debridement. If needed, however, skin can be harvested from the abdomen or thigh and used as a split-thickness and meshed graft.

We arrange office follow-up in most of our acute scrotal trauma patients about 6 weeks after initial presentation for an examination and ultrasonography. This allows us to ensure that any symptoms are improving and visualize the testis once the acute pathology is resolved. This is particularly true if there was no operative intervention to ensure that there is no other underlying testicular pathology masked by hematoma or testicular injury.

Vaginal Injury

Vaginal injuries in female patients are relatively uncommon and can generally be divided into two categories—straddle injuries and penetrative injuries. Although there is an AAST scoring system for both vaginal and vulvar injury (Tables 52.11 and 52.12), this is not often cited, and no other scoring systems that have been proposed are widely used (Onen et al., 2005a, 2005b).

TABLE 52.11

Vaginal Injury: American Association for the Surgery of Trauma Organ Injury Scale

Contusion or hematoma
Laceration, superficial (mucosa only)
Laceration, deep (into fat or muscle)

Laceration, complex, into cervix or peritoneum
Injury into adjacent organs (anus, rectum, urethra, bladder)

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

TABLE 52.12

Vulvar Injury: American Association for the Surgery of Trauma Organ Injury Scale

Contusion or hematoma
Laceration, superficial (skin only)
Laceration, deep (into fat or muscle)
Avulsion; skin, fat, or muscle
Injury into adjacent organs (anus, rectum, urethra, bladder)

Modified from Moore EE, Cogbill TH, Jurkovich GJ, et al. Organ injury scaling. III: Chest wall, abdominal vascular, ureter, bladder, and urethra. *J Trauma*. 1992;33(3):337–339.

Straddle injury is by far the most common etiology of vaginal trauma, accounting for about 80% of all injuries, and penetrating injuries make up about 5% (Dowd et al., 1994; Spitzer et al., 2008). Straddle injuries do not ordinarily result in perianal, hymen, or vaginal trauma (Saxena et al., 2014). These injuries are suggestive of a penetrating mechanism, intentional or not (Dowd et al., 1994).

Any history or sign of penetrating vaginal injury must raise suspicion of abuse and should prompt careful assessment of the etiology of the trauma. Signs of penetrative injury are associated with injury to neighboring anatomy (such as the bladder, urethra, anus, or rectum), internal vaginal injury, or hymenal injury. Hymenal injury in particular has been strongly correlated with sexual abuse (Bond et al., 1995; Heppenstall-Heger et al., 2003) and, when present, suggests abuse unless the event precipitating the injury was witnessed to be unintentional.

Injuries can be associated with boney pelvis fracture and concomitant injury to the urethra, bladder, and rectum. In these circumstances, examination under general anesthesia is indicated so that cystoscopy and vaginoscopy might be performed along with anoscopy by a general surgeon.

Management

Straddle injuries typically result in minor trauma to the labia minora, with most not requiring surgical intervention or a trip to the operating room. Minor injuries of the labia minora that are managed conservatively typically heal well without substantial scarring. Older patients that present acutely with larger injuries, particularly those involving the hymen, are more likely to require operative intervention particularly if associated with perineal bleeding, hematoma, or swelling (Scheidler et al., 2000; Spitzer et al., 2008).

In children, outward appearance of the genitalia may not necessarily reflect the underlying severity of the trauma or, in fact, that any trauma has even occurred (Heger et al., 2002). In a prospective study over 10 years, 94 children (81 females) were followed for anogenital trauma. Of the 81 females, more than one-half had injuries as a result of abuse. Only 15% of these had significant anatomic evidence of injury when examined later, suggesting that most heal without obvious scar. They did recommend repair of the posterior forchette in the acute setting to improve later healing of the vaginal introitus (Heppenstall-Heger et al., 2003). Injury to the urethra, bladder, anus, and rectum can be missed, and consideration to performing an examination under anesthesia should be given if there is a high suspicion for abuse (Okur et al., 1996).

Two papers described healing of hymenal and nonhymenal injuries in females who were of adolescent age and younger (McCann et al., 2007a, 2007b). In 239 nonhymenal injuries (113 of which were in prepubertal girls), most were secondary to abuse. Not surprisingly, superficial injuries such as abrasions, contusions, and superficial lacerations healed rapidly, and deep lacerations took several weeks. Hymenal injuries healed rapidly without evidence of scar, and most had no evidence of injury once healed. Thus, importantly, the lack of outward evidence of trauma does not preclude the possibility of a history of sexual abuse (Adams et al., 1994).

Key Points: Genital Injury

- Genital injury in children should raise suspicion for abuse.
- If abuse is suspected, concomitant injury to the rectum and anus should be ruled out.
- Most circumcision injuries can probably be avoided by ensuring that adhesions are properly reduced at the beginning of the procedure.
- Findings on ultrasonography consistent with testicular rupture should prompt strong consideration of surgical exploration.
- Straddle injuries make up the majority of vaginal injuries. Injuries to bladder, urethra, anus, rectum, hymen, and internal vaginal structures are suggestive of penetrative injury and should prompt evaluation for abuse.

Pediatric Urologic Oncology

Renal and Adrenal

Michael L. Ritchey MD, Nicholas G. Cost MD, Robert C. Shamberger MD

Neuroblastoma

Neuroblastoma is the most common extracranial solid tumor of childhood. Unfortunately, more than half of the children are seen initially with metastatic disease. Neuroblastoma is known to arise from cells of the neural crest that form the adrenal medulla and sympathetic ganglia. Tumors may occur anywhere along the sympathetic chain within the neck, thorax, retroperitoneum, or pelvis or in the adrenal gland: 75% arise in the retroperitoneum, 50% in the adrenal, and 25% in the paravertebral ganglia. The variety of locations where these tumors arise and the spectrum of their differentiation result in a wide range of clinical presentations and behaviors (Brodeur, 1991). These tumors can undergo spontaneous regression (Brodeur, 1991), differentiate to benign neoplasms, or exhibit extremely malignant behavior. Biologic factors have been defined that predict and explain much of the variance in behavior between tumors.

Epidemiology and Genetics

Incidence

Neuroblastoma accounts for 8% to 10% of all childhood cancers. In the United States, the annual incidence is 10 cases per 1 million live births. It is the most common malignant tumor of infancy. A review of 3666 children enrolled in the cooperative group trials of the Pediatric Oncology Group and the Children's Cancer Group showed a median age at diagnosis of 19 months (Brodeur and Maris, 2006): 36% were infants, 89% were younger than 5 years, and 98% were diagnosed by 10 years of age.

Genetics

There have been a number of familial cases reported that are postulated to represent an autosomal dominant pattern of inheritance (Knudson and Strong, 1972; Robertson et al., 1991). Although the median age at diagnosis of neuroblastoma is 19 months, in familial cases it is 9 months (Kushner et al., 1986). At least 20% of patients with familial neuroblastoma have bilateral adrenal or multifocal primary tumors, which are unusual in spontaneous cases. The risk for development of neuroblastoma in a sibling or offspring of a patient with neuroblastoma is less than 6% (Kushner et al., 1986). Linkage analysis in seven families with two or more first-degree relatives affected with neuroblastoma identified a single interval at chromosome 16p12-13 with consistent linkage (Maris et al., 2002). This suggested that a hereditary neuroblastoma predisposition gene may be located at this site and may explain the familial cases. Subsequent studies in these familial cases, which account for less than 1% of patients with neuroblastoma, have identified *PHOX2B* and *ALK* as hereditary predisposition genes (Mosse et al., 2004, 2008).

Constitutional Chromosome Abnormalities

Numerous karyotypic abnormalities have been found in neuroblastoma, and these are recognized to have prognostic significance. These changes occur in the form of chromosomal deletions, translocations, and cytogenetic evidence of gene amplification. Aneuploidy of the tumor DNA, an abnormal number of copies of the normal 23 chromosomes, occurs in a significant number of cases (55%) and is a favorable prognostic indicator when compared with tumors that have a normal or tetraploid number (Kaneko et al., 1987). **Amplification of the *MYCN* oncogene at 2p24 defined as greater than 10 copies of this gene is seen in roughly 20% to 25% of primary tumors and is an adverse prognostic indicator** (Look et al., 1991; Muraji et al., 1993). It is present in 40% of patients with advanced stage disease but in only 5% to 10% of children with low-stage disease (Brodeur et al., 1984). It is associated with rapid tumor progression and poor outcome from treatment. These findings have been so striking that neuroblastoma was the first tumor in which the intensity of chemotherapy for a patient was determined not only by the stage and histology of the tumor but also by its "biologic markers," which were primarily chromosomal (Matthay et al., 1998).

Deletion of the short arm of chromosome 1 (1p) is found in 25% to 35% of neuroblastomas and is an adverse prognostic marker (Brodeur et al., 1992; Caron et al., 1996). The deletions are of various lengths, but, in a series of eight cases, a consensus deletion included the segment 1p36.1-2, suggesting that a tumor suppressor may be present in this region; although the involved genes have not been identified conclusively, *CHD5* is a strong candidate for this role (Fujita et al., 2008; Maris et al., 2007; Weith et al., 1989). This deletion is present in 70% of advanced stage neuroblastoma, and it has been demonstrated to be an independent prognostic factor (Attiyeh et al., 2005). There have been reports of constitutional abnormalities involving the short arm of chromosome 1 (Laureys et al., 1990). It has been demonstrated that loss of heterozygosity (LOH) at 1p36 and Unb11q is independently associated with a worse outcome in patients with neuroblastoma (Attiyeh et al., 2005). (Unbalanced LOH implies LOH at markers on 11q with retention of 11p material, in contrast with “whole-chromosome” 11 LOH, where there is LOH at every marker along the chromosome.) Although the 1p deletions are seen in conjunction with advanced stage and *MYCN* amplification, the 11q deletions are rarely seen in tumors with *MYCN* amplification but are associated with other high-risk features and are predictive of poor outcomes in the subset of patients with low-stage disease without *MYCN* amplification (Spitz et al., 2006). An additional genetic abnormality, gain of one to three copies of 17q, often the result of translocation with chromosomes 1 or 11, has been demonstrated to correlate with more aggressive tumors (Bown et al., 1999). The break points vary, but the addition of a region from 17q22-qter is common, suggesting that genes replicated in this region provide an advantage (Schleiermacher et al., 2004). In multivariate analysis, gain of 17q was the most powerful prognostic factor, followed by the presence of stage IV disease and deletion of 1p.

Embryology and Spontaneous Regression

In 1963 Beckwith and Perrin coined the term *in situ neuroblastoma* for small nodules of neuroblasts found incidentally within the adrenal gland that are histologically indistinguishable from neuroblastoma. In situ neuroblastoma was found during postmortem examination in 1 of 224 infants younger than 3 months. This represents an incidence of approximately 40 to 45 times greater than that of clinical tumors, suggesting that these small tumors regress spontaneously in most cases. Subsequent studies have shown that these nodules of neuroblasts are found in all fetuses studied and generally regress (Ikeda et al., 1981). Neuroblastoma identified by prenatal ultrasonography (US) has also been shown to have a clinically favorable course (Ho et al., 1993).

The concept of in situ neuroblastoma has been used to support the argument that many neuroblastomas arise and regress spontaneously. This concept has been further supported by population-based studies in Quebec province and in Japan, where prospective screening of infants for neuroblastoma has been performed based on urinary catecholamine excretion. An increased number of children were identified with low-stage neuroblastoma, a higher frequency than present clinically, but resection of those tumors did not result in a decrease in the incidence of advanced-stage tumors seen at an older age (Hayashi et al., 1995;

Woods et al., 1996). A subsequent German Neuroblastoma Screening Study postponed screening until 10 to 19 months of age. Fewer early stage cases were identified, and a greater frequency of patients with unfavorable clinical and biologic features were identified, but there was no decrease in the mortality of these patients (Schilling et al., 2002). Evaluation of adrenal tumors resected in the neonatal period, whether cystic or solid, showed that in most, the “biologic markers” were favorable (Kozakewich et al., 1998). The highly favorable outcome of infants diagnosed with neuroblastoma in the population screening studies led to attempts at expectant observation. These trials demonstrated a high rate of spontaneous resolution (Yamamoto et al., 1998; Yoneda et al., 2001). Spontaneous regression of these perinatally identified lesions also has been demonstrated radiographically (Holgerson et al., 1996). These findings led to a prospective study by the Children's Oncology Group (COG) evaluating treatment of infants with adrenal masses identified in the perinatal or neonatal period in which expectant observation for infants with small lesions with favorable catecholamine ratios was encouraged and is discussed later.

Pathology

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma display a spectrum of histologic maturation and differentiation (Fig. 53.1). A grading classification of neuroblastoma, introduced in 1984 by Shimada and subsequently modified by him and others as the International Neuroblastoma Pathology Classification in 1999, has helped to define risk-based subtypes of ganglioneuroblastoma and neuroblastoma (Shimada et al., 1984, 1999a, 1999b). This revised system has been demonstrated to add independent prognostic information beyond the contribution of age that is one of the factors contained in the system (Sano et al., 2006). Ganglioneuroma is a histologically benign, fully differentiated counterpart of neuroblastoma. It is unclear whether ganglioneuroma arises de novo or by maturation of a preexisting neuroblastoma or ganglioneuroblastoma. Metastatic lesions from neuroblastoma have been observed to develop the histology of mature ganglioneuroma, supporting the latter theory (Hayes et al., 1989).

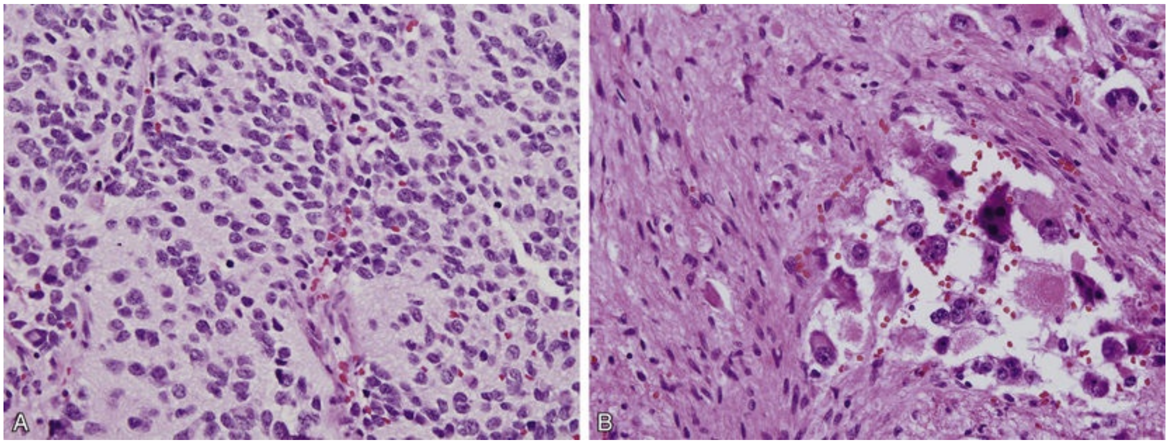

FIG. 53.1 (A) Poorly differentiated neuroblastoma with a minimal to moderate amount of neuropil. (B) Ganglioneuroblastoma with more than 50% of surface area occupied by Schwannian stroma on left. Lobule contains ganglion cells, immature ganglion cells, and poorly differentiated neuroblasts; only minimal neuropil is present within lobule. (Photo courtesy Dr. Harry Kozakewich.)

The Shimada classification is an age-linked histopathologic classification. One of its important aspects is determining whether the tumor is stroma poor or stroma rich. Patients with stroma-poor tumors with unfavorable histopathologic features have a very poor prognosis (less than 10% survival) (Shimada et al., 1984). Stroma-rich tumors can be separated into three subgroups: nodular, intermixed, and well differentiated. Tumors in the latter two categories more closely resemble ganglioneuroblastoma or immature ganglioneuroma and carry a higher rate of survival. The stroma-poor tumors can be divided into favorable and unfavorable subgroups based on the patient's age at diagnosis, the degree of histologic maturation, and the mitotic rate. When compared with other clinical features, these histologic patterns were independently predictive of outcome (Shimada et al., 1984).

In contrast to neuroblastomas, ganglioneuromas are most often diagnosed in older children and are usually located in the posterior mediastinum and retroperitoneum, with only a small number arising in the adrenal glands (Enzinger and Weiss, 1988). Ganglioneuromas often grow to a very large size before they cause symptoms as a result of compression of adjacent structures or extension into the spinal canal (Benjamin et al., 1972; Fig. 53.2). Because survival is not influenced by extent of resection, it should be used only in those patients in whom significant symptoms are present, and aggressive attempts at resection should be avoided (DeBernardi et al., 2008).

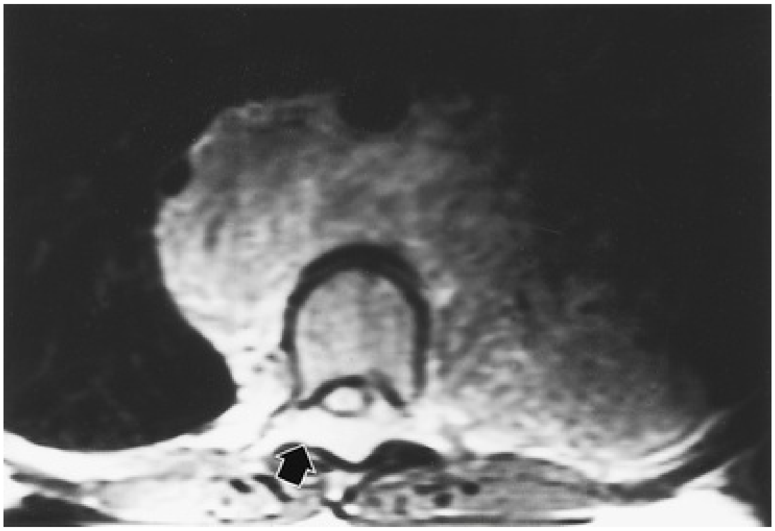

FIG. 53.2 MRI of child with thoracic ganglioneuroma extending into the spinal canal *(solid arrow)*.

Clinical Presentation and Pattern of Spread

The clinical manifestations of neuroblastoma vary widely. Most children have abdominal pain or a palpable mass, but others are identified as a result of manifestations of their metastatic disease, including bone or joint pain and periorbital ecchymosis. Thoracic lesions may produce respiratory symptoms of cough or dyspnea. Direct extension of the tumor into the spinal canal may produce neurologic deficits as a result of cord compression.

Most primary tumors arise within the abdomen (65%); the frequency of adrenal tumors is slightly higher in children than in infants. Physical examination often reveals a fixed, hard abdominal mass. Pelvic neuroblastoma arising from the organ of Zuckerkandl accounts for 4% of tumors (Haase et al., 1995). Extrinsic compression of the bowel and bladder can produce symptoms of urinary retention and constipation (Fig. 53.3).

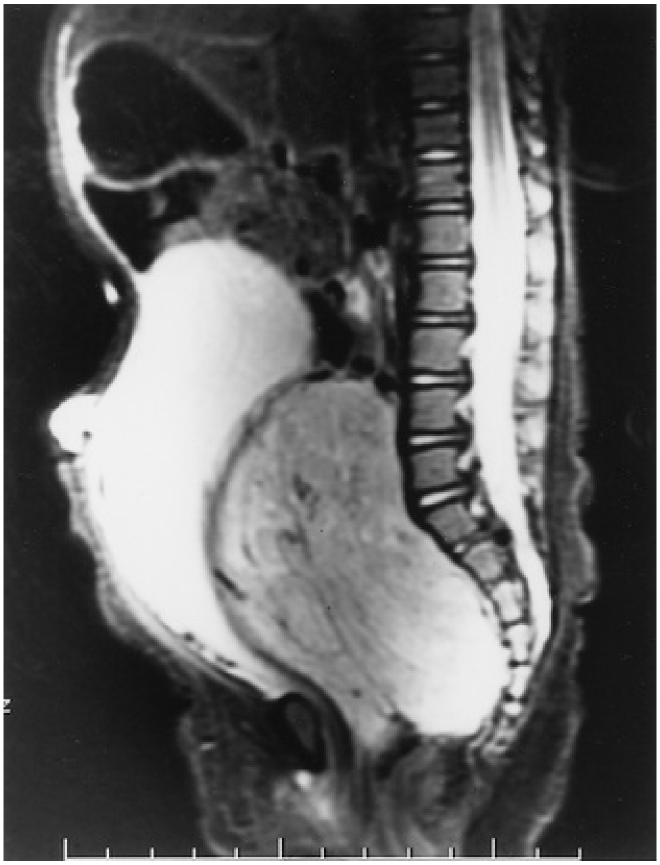

FIG. 53.3 MRI demonstrating compression of bowel and bladder by a pelvic neuroblastoma.

Metastases are present in 70% of patients with neuroblastoma at diagnosis and can be responsible for a variety of the clinical signs and symptoms at presentation. A number of unique paraneoplastic syndromes have been associated with localized and disseminated neuroblastoma. Symptoms produced by catecholamine release may mimic those seen in pheochromocytoma: paroxysmal hypertension, palpitations, flushing, and headache. Secretion of vasoactive intestinal peptide (VIP) by the tumor can produce severe watery diarrhea and hypokalemia (Cooney et al., 1982). Another unusual presentation of neuroblastoma is acute myoclonic encephalopathy, in which patients develop myoclonus, rapid multidirectional eye movements (opsoclonus), and ataxia. It is thought to result from an interaction of antibodies produced against the neuroblastoma to normal neural tissues (Connolly et al., 1997; Farrelly et al, 1984). Although this syndrome is associated with a favorable outcome from an oncologic perspective (Altman and Baehner, 1976), prolonged neurologic impairment, including learning disabilities and developmental delay, is the rule in 70% to 80% of these children, and symptomatic therapy is often required (Mitchell et al., 2002; Rudnick et al., 2001; Russo et al., 1997). Adrenocorticotropic hormone (ACTH) or steroids are the basis of most therapy, but other treatments include high-dose intravenous gamma globulin and cyclophosphamide. A recently completed protocol of the Children's Oncology Group evaluated the efficacy of cyclophosphamide plus steroids randomized to receive intravenous gamma globulin or not. The addition of IVIG to prednisone and risk-adapted chemotherapy improved opsoclonus/myoclonus response (de Alarcon et al., 2018).

Diagnosis

Laboratory Evaluation

When sensitive techniques are used, increased levels of urinary metabolites of catecholamines, vanillylmandelic acid (VMA) and homovanillic acid (HVA), are found in 90% to 95% of patients (Williams and Greer, 1963). Therapy with various modalities produces a reduction in catecholamine metabolite excretion in most patients (Gerson and Koop, 1974). These metabolites can be monitored to detect tumor relapse and response to therapy.

Anemia is noted in children with widespread bone marrow involvement. Studies suggest that marrow biopsies add substantially to the detection of marrow involvement by tumor, compared with marrow aspirates alone (Franklin and Pritchard, 1983). It is recommended that two marrow aspirates and two biopsies be performed for staging at presentation. In the future, neuroblastoma-specific immunocytology of marrow aspirates may obviate the need for marrow biopsies in most patients (Hsiao et al., 1990).

Imaging

Imaging studies play an important role in the evaluation of a child with neuroblastoma. **Plain radiographs may demonstrate a calcified abdominal or posterior mediastinal mass.** Computed tomography (CT) and magnetic resonance imaging (MRI) provide more information about the local extent of the primary tumors and vascular involvement. Invasion of the renal parenchyma is not common, but it can be detected radiographically by CT (Albregts et al., 1994). MRI has advantages over CT in the evaluation of intraspinal tumor extension, which is common in the paravertebral lesions (see Fig. 53.2), and in demonstrating the relationship between the major vessels and the tumor

(Azizkhan and Haase, 1993; Fig. 53.4). **The finding of intratumoral calcifications, vascular encasement, or both on preoperative CT may help distinguish neuroblastoma from Wilms tumor** (Dickson et al., 2008). Current Children's Oncology Group protocols require a radionuclide meta-iodobenzylguanidine (MIBG) scan for staging but no longer require the classic skeletal survey or bone scans. MIBG scans use ^{123}I-MIBG (Geatti et al., 1985), which is taken up by the adrenergic secretory vesicles of the tumor cells in primary and metastatic sites. MIBG scintigraphy can determine the extent of disease and detect tumor recurrence after completion of therapy (Geatti et al., 1985). ^{123}I-MIBG has been shown to be more sensitive than either ^{131}I-MIBG or bone scans in detecting tumor relapse (Kushner et al., 2009). For patients who have non-MIBG avid tumors, positron emission tomography (PET) scans are used. Osseous metastatic lesions occur most commonly in the long bones and skull.

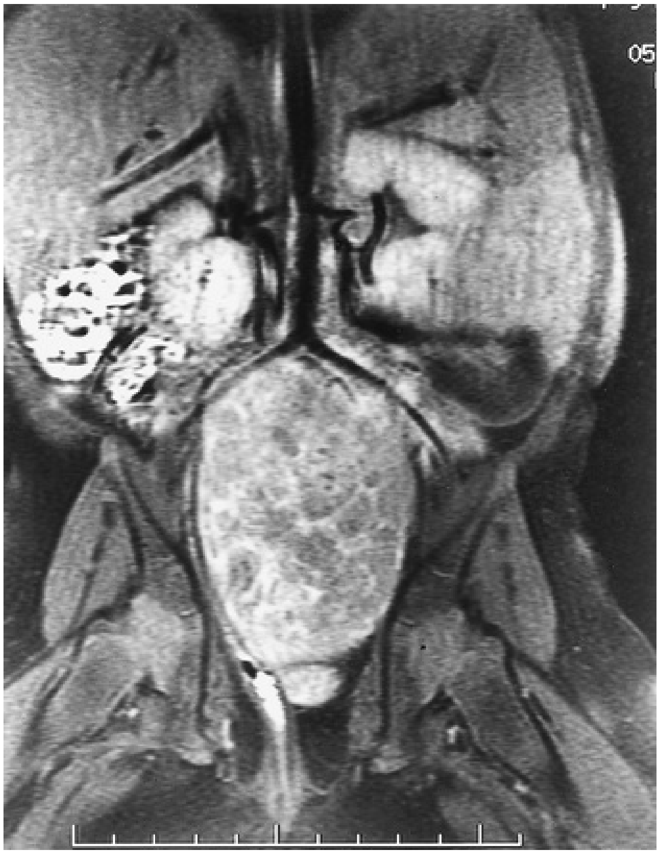

FIG. 53.4 MRI of pelvic neuroblastoma. The bifurcation of the aorta and iliac vessels are well delineated, showing the relationship to the mass.

Screening

Mass population screening for neuroblastoma has been widely used in Japan for more than 20 years (Nishi et al., 1987). The goal of screening programs is to detect disease at an earlier stage and to decrease the number of older children with advanced-stage disease, thereby improving survival. In fact, the children diagnosed as a result of screening studies have had almost uniformly favorable survival (>97%) (Suita, 2002). An increased number of infants younger than 1 year of age have been diagnosed through the mass screening program (Ishimoto et al., 1990), and most of these patients have lower-stage tumors (Sawada, 1992). Before mass screening, 20% of neuroblastoma cases were diagnosed before 1 year of age, compared with 55% after its implementation. However, the number of children older than 1 year of age diagnosed with advanced-stage disease has not decreased. These results suggest that the aggressive advanced-stage tumors in older children did not arise from the low-risk tumors seen in the infants less than 1 year of age.

There are biologic differences between tumors diagnosed by screening and those detected clinically (Hayashi et al., 1992). In one review of 48 cases discovered by screening, no tumors were observed to have amplified *MYCN* oncogene expression (Ishimoto et al., 1991), and in a second review of 20 infants, only one who did poorly had amplification (Hase et al., 2002). Furthermore, 80% had a diploid chromosome pattern, which is also associated with a favorable prognosis. On follow-up, all 48 patients were still alive without tumor. In another series of 357 patients whose tumors were diagnosed by mass screening, the overall survival rate was 97% (Sawada, 1992). Given the favorable biologic characteristics of tumors discovered by screening, it is possible that many would spontaneously resolve without therapy, particularly given the increased incidence of neuroblastomas seen in the screened population.

Two large prospective population-based studies were conducted in the Province of Quebec and in Germany. These studies demonstrated that urine screening at various ages was successful in identification of neuroblastoma, but there was no decrease in the occurrence of neuroblastoma in older children and its subsequent mortality (Schilling et al., 2002; Woods et al., 2002).

Staging

Staging of neuroblastoma is an important aspect of management. **The stage of the disease is a significant prognostic variable that determines adjuvant**

therapy in the cooperative group trials. The International Neuroblastoma Staging System (INSS) is based on clinical, radiographic, and surgical evaluation of children with neuroblastoma (Brodeur et al., 1993; Table 53.1). Earlier staging systems provided generally comparable results in terms of distinguishing low-stage, good-prognosis disease from high-stage, poor-prognosis disease. Use of a uniform international system, however, makes comparison of results from various studies much easier. The biggest differences arise when the various systems are applied to those with intermediate-stage disease.

TABLE 53.1

International Neuroblastoma Staging System

STAGE	DEFINITION
1	Localized tumor with complete gross excision with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive).
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline[a], with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin and/or other organs.
4S	Localized primary tumor (as defined for stage I, IIA, or IIB), with dissemination limited to skin, liver, and/or bone marrow (less than 10% tumor) in infants < 1 year of age.

[a] The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

An effort has been made to identify, preoperatively, those tumors that are resectable without significant surgical risks. The Localized Neuroblastoma European Study Group (LNESG) defined the radiographic criteria associated with higher surgical morbidity. They validated that the criteria's presence was associated with a lower rate of complete resection and a greater risk of surgical complications (Cecchetto et al., 2005). This finding has been confirmed by others (Simon et al., 2008). The International Neuroblastoma Risk Group (INRG) Task Force proposed a staging system based on tumor imaging rather than the extent of surgical resection to address this problem (Monclair et al., 2009). In this system, localized tumors are graded as L1 or L2 based on the absence or presence of 1 or more of 20 image-defined risk factors (IDRFs), which are related primarily to encasement of vessels or nerves. Metastatic tumors are termed stage M, and MS refers to INSS stage IV-(S) in children younger than 18 months of age, whereas in INSS the age cutoff was 12 months. These factors were found to be prognostic, and in 661 patients, those with L1 disease had a greater 5-year event-free survival (EFS) (90 ± 3%) compared with those with L2 disease (78 ± 4%, $P = 0.001$). A further description of these guidelines has been reported by this group (Brisse et al., 2011). Although a close correlation between presence of IDRFs and resectability of the tumor has been reported, others have not supported this finding (Günther et al., 2011; Rich et al., 2011). A follow-up from the LNESG of patients with localized disease demonstrated that the presence of IDRFs is associated with worse survival rates and higher rates of operative complications (Monclair et al., 2015). A SIOPEN study of children with unresectable neuroblastoma demonstrated that the IDRFs remained unchanged in 50% of patients receiving chemotherapy and that in fact 20% suffered the appearance of new IDRFs (Avanzini et al., 2017). They also identified that children with midline perivascular IDRFs had an increased incidence of operative complications but also lower EFS and overall survival (OS).

The International Neuroblastoma Risk Group Pretreatment Classification uses the Risk Group Classification (INRGSS), pathological findings, stage, age, and several of the biologic markers to best define the child's risk for progressive disease (Table 53.2; Cohn et al., 2009). Although the classification appears complex, it provides the most accurate assessment of how intense the chemotherapy and radiotherapy must be to cure the child. The challenge with any staging system that uses extent of resection as a component, however, is that a more aggressive approach to a tumor at one institution may result in a different stage for the child than if treated at another.

TABLE 53.2

International Neuroblastoma Risk Group (INRG) Classification System

INRG STAGE	AGE (MONTHS)	HISTOLOGIC CATEGORY	GRADE OF TUMOR DIFFERENTIATION	*MYC*
L1/L2		GN maturing		
		GNB intermixed		
L1		Any, except the above		NA
				Amp
L2	<18	Any, except the above	NA	No
				Yes
	≥18	GNB nodular neuroblastoma	Differen	NA
			Poorly differen or undifferen	NA
				Amp
M	<18			NA
	<12			NA
	12 to <18			NA
	<18			Amp
	≥18			
MS	<18			NA
				NA
				Amp

Blank field = any; Diploid – DNA index ≤ 1.0; Hyperdiploid – DNA index > 1.0 and includes near-triploid and near-tetraploid; very-low–risk 5-year EFS >85%; low-risk 5-year EFS >75% to ≤85%; intermediate-risk 5-year EFS ≥50% to ≤75%; high-risk 5-year EFS <50%; L1 localized tumor confined to one body compartment and with absence of image-defined risk factors (IDRFs); L2 locoregional tumor with presence of one or more IDRFs; M distant metastatic disease except stage MS; MS metastatic disease confined to skin, liver, and/or bone marrow in children <18 months of age.

Amp, Amplified; *Differen,* differentiating; *GN,* ganglioneuroma; *GNB,* ganglioneuroblastoma; *NA,* not amplified; *Undifferen,* undifferentiating.

Prognostic Factors

Many variables affect the prognosis of neuroblastoma. In addition to the clinical features, there are now many biologic factors that can be used to stratify patients for treatment.

Clinical Variables

Age remains an important indicator of outcome, as originally reported by Breslow (Breslow and McCann, 1971). **Children age 1 year or younger have been recognized historically to have a better survival than older children**

(Nitschke et al., 1988)**. This may be attributed to the presence of favorable biologic parameters in tumors diagnosed at this age.** Retrospective reviews have suggested that age is a more “continuous” prognostic variable and that a cutoff of 460 days maximized the outcome difference between the younger and older patients (London et al., 2005). More recent data from the INRG suggest that an age at diagnosis cutoff of greater than 18 months is associated with a higher risk of disease recurrence (Moroz et al., 2011). Teenagers and adults with neuroblastoma have a particularly indolent and relentless disease (Gaspar et al., 2003; Kushner et al., 2003). **The site of origin is also of significance, with better survival noted for nonadrenal primary tumors** (Haase et al., 1995). Most children with thoracic neuroblastoma are seen at a younger age with localized disease and have improved survival even when corrected for age and stage (Adams et al., 1993). Tumors at this site are less likely to have *MYCN* amplification and more likely to have a DNA index greater than 1.0, both favorable prognostic indicators (Morris et al., 1995).

Stage of the disease is a powerful independent prognostic indicator. All stage I patients with complete resection of the primary tumor survive. Stage II patients also have a favorable survival prospect, even though there may be incomplete excision (Matthay et al., 1989). Children with advanced regional disease, stages III or IV, fare less well and require more intensive treatment. The proportion of patients with localized, regional, or metastatic disease is age dependent (Nitschke et al., 1988). The OS for stages I, II, or IV-S was a range of 75% to 90%, whereas those children with stage IV disease had a historical 2-year disease-free survival range of 19% to 30% despite intensive therapy, including bone marrow transplantation. The outcome for infants younger than 1 year of age is substantially better than for older patients with the same stage of disease.

Stage IV-S (S meaning special) is a distinct category referring to infants with small primary tumors and liver, skin, and bone marrow metastases without radiographic evidence of bone metastases. This group of patients has a good prognosis, with OS ranging from 80% to 88%. The INSS criteria later restricted this stage to children with less than 10% bone marrow involvement (Brodeur et al., 1993). This stage accounts for 7% to 10% of all cases of neuroblastoma. Many of these tumors undergo spontaneous regression (Evans et al., 1987; Haas et al., 1990). In general, the tumors in infants with stage IV-S neuroblastoma have favorable prognostic findings not typically seen in children with stage IV disease (Hachitanda et al., 1991; Nickerson et al., 2000). Poor outcome in stage IV-S patients is associated with elevated serum neuron-specific enolase (>100 nmol/mL), ferritin (>280 ng/mL), urinary dopamine levels (>2500 nmol/mmol creatinine), as well as *MYCN* amplification and chromosome 1p deletion (Schleiermacher et al., 2003). Most deaths in this group are in infants under 2 months of age with extensive abdominal involvement and respiratory compromise or disseminated intravascular coagulation (Nickerson et al., 2000).

Biologic Variables

The presence of homogeneously staining regions and double-minute chromosomes was noted in approximately one-third of neuroblastoma tumors. These abnormalities are cytogenetic manifestations of gene amplification, and it was subsequently found that the *MYCN* oncogene was mapped to these regions. The association of *MYCN* amplification with the pathogenesis of neuroblastoma is unclear, but *MYCN* amplification is almost always present at the time of diagnosis (Brodeur, 1991). Seeger et al. (1985, 1988) showed that ***MYCN* amplification is associated with rapid tumor progression and a poor prognosis. Amplification is found in 5% to 10% of patients with low-stage or stage IV-S** (Hachitanda et al., 1991) **but in 30 to 40% of those with advanced-stage disease** (Brodeur, 1990; Brodeur and Fong, 1989). **The poor prognosis associated with *MYCN* amplification is independent of patient age or stage of disease at presentatio**n (Iehara et al., 2006). However, not all patients with a poor outcome have *MYCN* amplification. Many advanced-stage tumors lack *MYCN* at diagnosis, and recurrence or progression of disease develops in most of these patients.

DNA content of tumor cells and ploidy number has been reported to have prognostic value in patients with neuroblastoma (Cohn et al., 1990). Studies of DNA content measured by flow cytometry showed that a “hyperdiploid” karyotype (or increased DNA content) was associated with a favorable outcome (Kusafuka et al., 1994; Look et al., 1984). DNA diploidy and tetraploidy were associated with decreased survival. A review of 2660 children with localized neuroblastoma registered with the International Neuroblastoma Risk Group database evaluated tumor ploidy in children with *MYCN*–amplified tumors (Bagatell et al., 2009). They reported an improved prognosis in children with hyperdiploid tumors compared with diploid tumors. This could be used to identify children for reduction in the intensity of their therapy. A full INRG analytic cohort of 8800 patients from North America, Europe, and Japan provided an extensive analysis of the survival implications of multiple genetic characteristics (Cohn et al., 2009). Again, *MYCN* status was the most powerful predictor of EFS and OS along with ploidy, 11q and 1p status, and to a lesser extent 17q gain.

Deletions of the short arm of chromosome 1 have been found in 70% to 80% of the near-diploid tumors that have been karyotyped (Brodeur, 1990; Brodeur and Fong, 1989). Preliminary studies suggest a correlation between 1p deletion and poor survival (Brodeur and Fong, 1989; Hayashi et al., 1989). Children currently treated on protocols of the COG are assigned to a risk group that is determined by age, stage of disease, *MYCN* status, histologic grade, and DNA ploidy (Katzenstein et al., 1998). Other factors that have been demonstrated to have prognostic significance, although they are often associated with these genetic abnormalities, include expression of the gene encoding the high-affinity nerve growth factor receptor (termed *TRKA* proto-oncogene) and the low-affinity nerve growth factor receptor (Tanaka et al., 1995). Both are favorable prognostic predictors and are inversely related to amplification of *MYCN* oncogene (Nakagawara et al., 1993). Lack of expression of CD44 glycoprotein on the tumor cell surface and increased levels of serum ferritin, serum neuron-specific enolase, and serum lactate dehydrogenase are adverse prognostic factors (Chan et al., 1991; Silber et al., 1991). They have not, however, been shown by multivariate analysis to be independently predictive from age, stage, ploidy, and *MYCN* status. Telomere length has also been described as a significant prognostic parameter, and in a cohort of high-risk patients, it was the sole significant parameter that identified a group of patients with a favorable prognosis (Ohali et al., 2006).

Treatment

The treatment modalities primarily used in the management of neuroblastoma are surgery, chemotherapy, and radiation therapy. The role of each in individual patients varies depending on tumor stage, age, and biologic prognostic factors. These can be used to stratify patients into favorable and unfavorable categories by risk group (see Table 53.2).

Surgery

The goals of surgery are to establish the diagnosis, stage the tumor, excise the tumor (if localized), and provide tissue for biologic studies. Resectability of the primary tumor should take into consideration tumor location,

mobility, relationship to major vessels and nerves (IDRFs), and overall prognosis of the patient. Neoadjuvant chemotherapy, given the efficacy of modern agents, is successful in reducing the size of primary tumors and enhancing their resectability. Sacrifice of vital structures to achieve resection at diagnosis should be avoided, particularly in young children in whom prognosis is excellent.

Low-Risk Disease (Stages I, II, and IV-S).

Children with stage I neuroblastoma have a disease-free survival rate of greater than 90% with surgical excision alone (DeBernardi et al., 1995; Nitschke et al., 1988; O'Neill et al., 1985). **Chemotherapy is indicated only in the event of recurrence unless the child has *MYCN* amplification and unfavorable histology.** The Pediatric Oncology Group reviewed 101 children with localized neuroblastoma who had complete gross excision of the primary tumor (Nitschke et al., 1988). Nine patients experienced relapse, but 6 were salvaged with chemotherapy. Radiation therapy has no role in this subset of patients. With current use of the risk factor grading, those children with recurrence in the past may be identified now as the small number with adverse biologic markers. In a comparable study from the Children's Cancer Group, 374 stage I and II patients were treated primarily by resection (Perez et al., 2000). EFS and OS for stage I patients were 93 ± 3% and 99 ± 1%, respectively, compared with 81 ± 4% and 98 ± 2% for stage II patients, respectively. Supplemental treatment was required in only 10% of stage I and 20% of stage II patients, and excellent OS was achieved in the stage II patients. *MYCN* amplification, unfavorable histology, age greater than 2 years, and positive lymph nodes predicted a lower OS. The Children's Oncology Group (COG) conducted a trial of asymptomatic INSS stages 2a and 2b patients treated with surgery alone (Strother et al., 2012). Chemotherapy on this study was reserved for patients with symptomatic disease or in those considered at risk for its development, or those with less than 50% resection with unresectable progressive disease after surgery. For all 915 enrolled patients, the 5-year EFS and OS were 89% ± 1% and 97 ± 1%. In the cohort with IIb disease, the EFS and OS were significantly lower for those with unfavorable histology or diploid tumors, and OS was significantly lower for those 18 months and older. The 5-year OS for patients with stage I and IV-S were 99% ± 1% and 91% ± 1%, respectively; 11.1% of patients observed after surgery experienced recurrence or progressive disease.

Radical resection resulting in removal of normal organs, particularly the kidney, is not justified in this group of patients. Radiation of the local tumor bed has been advocated for treatment of residual disease in stage II cases. However, a review of 156 patients with stage II neuroblastoma found a 90%, 6-year, progression-free survival rate regardless of whether radiation therapy was used (Matthay et al., 1989). Therefore radiation should be reserved for those relapsed patients who fail to respond to either primary or secondary chemotherapy. In stage III disease, or in stage II with extensive tumor around the kidney and renal vessels, preoperative treatment with chemotherapy significantly decreases the risk of nephrectomy as a result of resection of the tumor (Shamberger et al., 1998; Fig. 53.5). **The generally favorable behavior of IV-S disease has been explained by our current knowledge of the significance of biologic markers. The majority of these infants have tumors with entirely favorable markers, explaining their favorable behavior. However, a small fraction have adverse markers; these children have progressive disease that often is fatal.** Resection of the primary tumor is not mandatory (Evans et al., 1987; Nickerson et al., 1985). Although excellent survival has been reported after surgery (Martinez et al., 1992), information regarding histologic prognostic factors was not available for all of these patients. In a review of 110 infants with stage IV-S disease, the entire cohort had an estimated 3-year survival rate of 85% ± 4% (Katzenstein et al., 1998). This rate was significantly decreased to 68% ± 12% for infants whose tumors were diploid; to 44% ± 33% for those with *MYCN* amplification; and to 33% ± 19% for those with unfavorable histology. There was no statistical difference in survival rate for infants who underwent complete resection of their primary tumor compared with those who had partial resection or only biopsy (Katzenstein et al., 1998; Nickerson et al., 2000; von Schweinitz et al., 2002). Patients with extensive metastatic disease and *MYCN* amplification represent a high-risk group (Martinez et al., 1992). These patients should be considered for a more intensive treatment with multimodal therapy, according to the risk group classification (see Table 53.2) (Schleiermacher et al., 2003). Those with favorable biologic markers and no symptoms can be followed with supportive care and limited chemotherapy. Intensive chemotherapy is reserved for those with adverse markers, although these infants do poorly even with therapy.

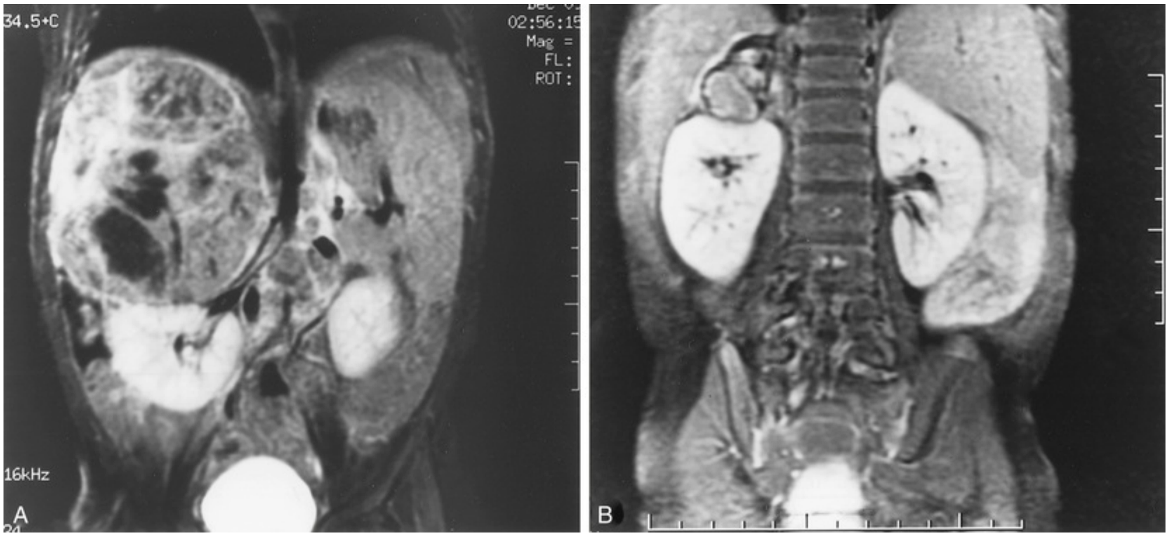

FIG. 53.5 MRI before and after chemotherapy showing marked reduction in size of right suprarenal neuroblastoma. (A) Before chemotherapy. (B) After chemotherapy.

Perinatal Neuroblastoma.

Based on the favorable outcomes of infants identified with neuroblastoma from the screening studies discussed earlier and the favorable biology of these tumors, a prospective study was performed by the COG to assess the outcome of expectant observation for neuroblastoma in young infants. Infants were enrolled who were under 6 months of age with small adrenal masses (≤16 mL in volume if solid or ≤65 mL if the mass was at least 25% cystic) and no evidence of spread beyond the primary tumor (Nuchtern et al., 2012) was found. Serial abdominal sonograms and urinary catecholamine levels were obtained during a 90-week interval. A 50% increase in the volume of the mass, urine catecholamine values, or the homovanillic acid–to–vanillylmandelic acid ratio greater than 2 were referred for surgical resection: 87 infants were enrolled, 83 families elected observation, and 4 chose immediate surgery. Sixteen infants on the observation arm ultimately had surgery; 8 had INSS stage I neuroblastoma, 2 had higher-stage neuroblastoma (IIB and IV-S), 2 had a low-grade adrenocortical neoplasm, 2 had adrenal hemorrhage, and 2 had extralobar pulmonary sequestration. The 2 adrenal cortical tumors were resected because of a greater than 50% increase in tumor volume. The 3-year EFS for a neuroblastoma event was 97.7% ± 2.2% within the entire cohort of infants. The 3-year OS was 100% with a median follow-up of 3.2 years. Following this protocol, 81% of the infants avoided resection, supporting the role of expectant observation in this selected population. Based on the success of the first trial with fairly restrictive entry criteria, a follow-up study was developed in which infants can be enrolled who are under 12 months of age at presentation with suspected lesions at any site that are under 5 cm in greatest diameter. For non-adrenal primary tumors, MIBG update in the tumor or elevated catecholamine levels must be present. Similar indications for surgical intervention are used from the initial study. Until this approach is established as safe, infants should be managed in this manner only if enrolled in a therapeutic study.

Intermediate and High-Risk Disease (Stages III and IV).

There is debate regarding the extent of surgical resection required for stage III lesions. A report from the Children's Cancer Group of 58 patients with stage III disease found that 8 of 12 patients with initial complete excision, and 12 of 14 with subsequent resection of the primary tumor, were long-term survivors (Haase et al., 1989). This result contrasts with only 9 of 32 survivors among patients in whom complete tumor excision could not be accomplished. Significant morbidity was reported in association with the surgical procedures, including 21 major complications. The Italian Cooperative Group for Neuroblastoma found that complete resection after chemotherapy of extensive unresectable neuroblastoma was associated with improved survival, compared with partial resection only (Garaventa et al., 1993). Similar results have been noted by others (Fischer et al., 2017; LeTourneau et al., 1985; O'Neill et al., 1985; Powis et al., 1996). It has been suggested by some that even children with stage III disease do not need cytotoxic therapy if the biologic marker *MYCN* amplification is not present (Kushner et al., 1996). These results are not widely accepted, however, and confirmatory studies are required before this policy can be widely adopted.

Children with bulky pelvic tumors generally do well even with limited residual disease (LeClair et al., 2004). Extensive surgery at this site has been associated with long-term neurologic sequelae; thus the extent of resection must be balanced against this morbidity (Cruccetti et al., 2000).

A study from the COG of intermediate-risk patients attempted to decrease the intensity of therapy while maintaining outcomes (Baker et al., 2010). Criteria for enrollment into this study included intermediate-risk neuroblastoma without *MYCN* amplification, including infants younger than 365 days of age with stage III or IV disease, children older than 365 days of age who had stage III tumors with favorable histopathological features, and infants who had stage IV-S disease with a diploid DNA index or unfavorable histopathological features. Children received four active agents in this study: cyclophosphamide, doxorubicin, carboplatin, and etoposide. They received 4 cycles if they had favorable biology or 8 cycles if they had unfavorable biology. Radiotherapy was used only for progressive disease or in patients with an unresectable primary tumor with unfavorable prognostic features. The 3-year estimate of OS for the entire group was 96% ± 1%; 98% ± 1% for those with favorable biologic features, and 93% ± 2% for those with unfavorable biologic features. These findings supported the reduction in therapy for this cohort of patients. Complete data regarding surgical intervention were available in 235 patients. Gross total resection was achieved in 89 patients, near total resection (>90% of the tumor) in 51, major resection (>50% of the tumor) in 26, and limited resection (≤50% of the tumor) in 54. **No significant difference was demonstrated in OS according to the extent of resection (complete vs. incomplete; *P* = 0.37); 28% of patients had one or more complications.**

A report from Memorial Sloan Kettering Cancer Center of children with stage III, non-*MYCN*–amplified disease with gross residual disease after initial surgery demonstrated that these patients could be safely observed and maintained excellent OS without use of cytotoxic therapy (Kushner et al., 1996). Similar results were found in the German neuroblastoma 97 study, in which infants with stage II or III *MYCN* non-amplified tumors who had incomplete resections were observed after surgery without chemotherapy. Regression of the residual masses without additional treatment was seen in 32 of 55 patients. Tumors that recurred or progressed were responsive to therapy with a 3-year OS rate of 98% (Hero et al., 2008).

Unfortunately, more than half of all newly diagnosed patients with neuroblastoma have high-risk disease. There is conflicting evidence regarding the benefit of extensive resection in children with stage IV disease between studies that support (Adkins et al., 2004; Chamberlain et al., 1995; DeCou et al., 1995; Haase et al., 1991; Koh et al., 2005; Kuroda et al., 2003; LaQuaglia et al., 1994, 2004; LeTourneau et al., 1985; McGregor et al., 2005; Tsuchida et al., 1992; Vollmer et al., 2017; von Allmen et al., 2005; Yokoyama et al., 1995) and those that refute that approach (Adams et al., 1993; Castel et al., 2002; Kaneko et al., 1997; Kiely, 1994; Losty et al., 1993; Matsumura et al., 1988; McGregor et al., 2005; Simon et al., 2013; Sitarz et al., 1983; von Schweinitz et al., 2002). In a retrospective review, Kiely (1994) compared the results of radical tumor resection with those of more conventional surgery in patients with stages III and

IV disease. He found no difference in survival between 46 patients treated with radical surgical procedures and 34 patients treated with more conventional surgery. Shorter et al. (1995) also did not find any evidence that the extent of surgical resection had an impact on the survival of stage IV patients. Simon et al. (2013) reported the results of the German cooperative trial NB97 that evaluated the role of surgery (upfront and post-neoadjuvant therapy) in patients older than 18 months with stage IV disease: 278 patients were evaluated. Their data suggested that neither upfront surgery nor operations performed post neoadjuvant therapy produced a positive impact on EFS, local progression-free survival, or OS. In contrast, von Allmen et al. (2005) reported on the local control of 76 patients treated at two institutions with the same treatment protocol and a consistent surgical approach. They found that aggressive surgery followed by local radiotherapy provided excellent local tumor control with no isolated local relapse in patients who had greater than 90% resection (60 of 76 children).

Subsequently, von Allmen et al. (2017) reviewed 220 patients treated on the COG study A3973 with high-risk neuroblastoma. In this cohort the blinded radiographic central imaging review for completeness of resection was compared with the surgeon's assessment. Concordance between surgeon's assessments and the radiographic assessment was low, 63%. Nonetheless, the clinical assessment of resection extent of greater than or equal to 90% (in 154 patients) compared with resection of less than 90% (in 66 patients) after adjustment for *MYCN* amplification or diploidy was associated with longer EFS and lower clinical incidence of local progression but had no effect on OS. In these nonrandomized studies, it has been difficult to determine whether improved survival in those with complete resection has been due to the more favorable intrinsic biology of the tumor, allowing resection or truly because of the completeness of resection. LaQuaglia has assessed the results in 33 non-redundant studies, which provided adequate surgical data for analysis of survival (LaQuaglia et al., 2014). The analysis included 2599 patients for the survival analysis and 412 in the analysis of local progression. Meta-analysis revealed that the relative risk of mortality for stage III and IV patients who had more than 90% resection was 0.67 (95% CI 0.59–0.77) compared with those with a lesser resection. For stage IV patients alone the relative risk was 0.75 (95% CI 0.62–0.92). The relative risk of local recurrence or progression in patients with stage IV disease was 0.38 (95% CI 0.27–0.53) for those undergoing extensive primary resection compared with those who did not.

As the intensity of the therapy increases (including the use of autologous bone marrow transplantation) and control of distant metastasis improves, the impact of maximal local control may become apparent. The combination of gross total resection and external beam irradiation has achieved local control in 84% to 90% of children (Kushner et al., 2001; Wolden et al., 2000). In another series of reports, intensive chemotherapy followed by double autologous bone marrow transplantation, aggressive surgical resection, and radiotherapy has achieved an OS of 56% and a local recurrence rate of only 2.6% (Marcus et al., 2003; von Allmen et al., 2005).

Usually the safest approach for advanced tumors is to defer resection until after initial chemotherapy (Berthold et al., 1989; Black et al., 1996; LaQuaglia et al., 1994; Shamberger et al., 1991; Shochat, 1992). **The tumors are smaller and firmer, with less risk of rupture and hemorrhage after chemotherapy, resulting in a decreased rate of complications, particularly nephrectomy** (Shamberger et al., 1998; see Fig. 53.5). One specific complication encountered after resection of extensive tumor surrounding the celiac axis and the superior mesenteric artery is diarrhea (Kiely, 1994). It is thought to result from resection of the autonomic nerves to the gut found anterior to the aorta at the base of the superior mesenteric artery and the celiac axis (Rees et al., 1998). The second frequent complication after extensive resection is chylous ascities resulting from resection of the involved retroperitoneal lymph nodes. This is generally a self-limited problem, but initial extensive abdominal distention may require intervention (Qureshi et al., 2016). Preoperative chemotherapy does appear to increase the proportion of children able to achieve a complete resection (Adkins et al., 2004).

Surgery usually is performed 13 to 18 weeks after initiation of chemotherapy, allowing three to four courses of treatment (Azizkhan and Haase, 1993). Some tumors remain inoperable even after chemotherapy.

Infants under 1 year of age with extensive local disease or stage IV disease make up a special subset of patients. They have historically fared much better than children older than 1 year of age with comparable disease, but not as well as infants with stage IV-S disease. It is now recognized that biologic markers can be used to identify which infants have high-risk disease and require intensive therapy and which will have intermediate-risk disease requiring less intensive therapy. The SIOPEN Infant Neuroblastoma European Study reported 120 infants with localized tumors and no *MYCN* amplification who were deemed unresectable based on IDRFs (Rubie et al., 2011). These infants were treated with low-dose cyclophosphamide and vincristine (VCR) repeated once to three times every 2 weeks until surgical excision could be safely performed. Infants with either one threatening symptom or an insufficient response were given carboplatin and etoposide (CaE) sometimes followed by vincristine, cyclophosphamide, and doxorubicin. Seventy-nine received the two-drug therapy with VCR and 49 received CaE because of insufficient response. Thirty-two infants had threatening symptoms and of these 30 received CaE. Anthracyclines were used in 46 infants. Surgery was performed in 102 infants leading to gross surgical excision in 93. Relapse occurred in 12 patients (9 local and 3 distant). The 5-year OS and EFS were 99% ± 1% and 90% ± 3%, respectively. The low-dose chemotherapy without an anthracycline was effective in 62% of these infants with an unresectable tumor and no *MYCN* amplification.

In a large cohort (134 infants), *MYCN* amplification, serum ferritin, Shimada histopathologic classification, and bone marrow involvement by immunocytology were analyzed. Although each factor had prognostic significance by univariate analysis, only *MYCN* amplification was significant by multivariate analysis; the EFS for infants without *MYCN* amplification was 93% ± 4% versus 10% ± 7% in those with amplification despite intensive therapy (Schmidt et al., 2000).

Clinical trials in Europe evaluated these infants without *MYCN* amplification and achieved excellent survival (OS of 97.6% at 2 years) without chemotherapy in those with primaries extending across the midline or a positive skeletal survey (DeBernardi et al., 2009). Infants with overt metastases to the skeleton, lung, and central nervous system (CNS) were treated with a minimum of four chemotherapy courses and achieved a 2-year OS of 95.6%.

Chemotherapy

A variety of multiagent treatment regimens have been developed to treat high-risk patients with neuroblastoma that use a combination of intensive induction therapy, myeloablative consolidation therapy with stem cell support, and biologic therapy to control minimal residual disease. The goal of this treatment intensification in a sequence of protocols is better disease control, and 5-year survival rates have gone from less than 15% to 30% to 40% (Philip et al., 1997). Although initial response rates are improving, with a prolonged time to progression of disease, relapse continues to be a major problem. A meta-analysis of 44 trials showed a correlation between dose intensity and treatment efficacy including improved response and survival (Cheung et al., 1991).

An induction regimen developed at Memorial Sloan-Kettering Cancer Center has been widely used in subsequent protocols. It used cycles of cyclophosphamide, vincristine, and doxorubicin alternating with cycles of cisplatin and etoposide. In their single institution study Kushner et al. (1994) reported complete response rate of 63% and a complete plus very good partial response rate of 87% in 24 patients. The dose intensification of chemotherapy required for local tumor control results in significant myelosuppression, limiting the amount of therapy that can be given. This has prompted the use of autologous bone marrow transplantation after sublethal chemotherapy or total-body irradiation. The use of marrow-ablative chemoradiotherapy followed by autologous marrow reinfusion has resulted in complete remission in up to 50% of patients with stage IV disease (Dinndorf et al., 1992; Grupp et al., 2000; Matthay et al., 1995; Moss et al., 1987; Mugishima et al., 1994; Seeger et al., 1991). However, a significant problem is the risk for late relapse. The randomized clinical trial of the German Society of Paediatric Oncology and Hematology of high-risk neuroblastoma showed improved EFS at 3 years with myeloablative therapy and autologous stem cell rescue compared with maintenance chemotherapy (Berthold et al., 2005). These results were similar to those of the COG study (Matthay et al., 1999). Unfortunately, the OS rates were not statistically different in either study at initial report. An update of the latter study, however, reveals that the 5-year OS of the patients receiving the autologous bone marrow transplant was improved (Matthay et al., 2009).

A subsequent study by the COG addressed the issue of the need for “purging” of the bone marrow before return to the patient to remove any potential remaining neuroblastoma cells (Kreissman et al., 2013). This study was terminated when interim analysis showed no difference in outcome between the two groups. A further study addressed the benefit between a single versus a paired autologous transplant to see if additional intensification would improve outcome. It was demonstrated that tandem versus single myeloablative therapy improves 3-year EFS in children with high-risk neuroblastoma (Park et al., 2016).

Recent trials in COG have piloted a strategy of using non–cross-resistant chemotherapy to further improve induction response rates. Topotecan, a topoisomerase-1 inhibitor has shown activity against neuroblastoma in phase I and II trials. In a COG feasibility trial high-dose topotecan was added to the Memorial Sloan-Kettering induction backbone (Park et al., 2011). Thirty-one patients were enrolled and the combination was well tolerated without unexpected toxicity. Fifteen of 31 patients (48%) achieved a complete or very good partial response. This regimen was added in a non-randomized fashion in the large phase III trial between single and tandem transplantation.

The presence of osseous disease has long been recognized as an adverse prognostic finding, particularly after induction therapy. A multivariate analysis of 549 patients with high-risk neuroblastoma in the European Bone Marrow Transplantation Solid Tumor Registry demonstrated that persistent cortical bone lesions ($P = 0.004$) and bone marrow involvement ($P = 0.03$) were the only independent adverse prognostic factors (Ladenstein et al., 1998). More recent retrospective studies of patients treated on COG A3973 assessed a "semiquantitative" MIBG score using the Curie scoring system. Patients who had a Curie score greater than 2 at the end of induction (n = 52) had a significantly decreased EFS compared with patients who had Curie scores of 2 or less (3-year EFS 15.4% ± 5.3% vs. 44.9% ± 3,8%, $P < 0.001$) (Yanik et al., 2013). This finding was particularly stark for patients with *MYCN* amplification (6 patients), in whom 3-year EFS was 0.

The presence of bulky disease results in increased failure. Tumor debulking with surgery or radiation therapy is warranted before autologous bone marrow transplantation. There are many questions yet to be resolved about this modality of treatment. Toxicity of bone marrow transplantation can be lethal, and the long-term complications in patients with successful transplantation are unknown. However, these risks are acceptable given that long-term survival is difficult to achieve without such intensive therapy.

Additional new agents in phase I and II trials for relapsed neuroblastoma include temozolomide and irinotecan (Kushner et al., 2006; Rubie et al., 2006; Simon et al., 2007). As efficacy is established, they will be advanced into clinical trials for high-risk tumors with a goal to improve the overall outcome.

New Innovative Biologic Therapies

Double autologous bone marrow transplantation has allowed the use of myeloablative therapies, but the maximum benefit to that approach has been reached. 13-cis-retinoic acid produces differentiation of neuroblastoma in cell cultures including cultures of recurrent tumors. It was given for a 6-month period after cytotoxic therapy in children with advanced-stage disease and significantly decreased the frequency of relapse (Matthay et al., 1999). Long-term follow-up has shown that the 5-year OS was improved (Matthay et al., 2009). Antibody therapy against the GD2 disialoganglioside cell surface marker uniformly expressed in neuroblastoma has been shown to be an effective adjuvant therapy in combination with granulocyte-macrophage colony-stimulating factor and interleukin-2 along with 13-cis-retinoic acid after autologous bone marrow transplant compared with 13-cis-retinoic acid alone (Yu et al., 2010). More recent studies have combined antibody therapy with a "backbone" of irinotecan and temozolomide, a pair of newer agents not included in front-line therapy. In one study these agents were combined with either antibody to GD2 or temsirolimus, an mTOR inhibitor that has a role in regulation of protein synthesis and cell proliferation (Mody et al., 2017). In this randomized study of relapsed patients the combination with the antibody to GD2 was effective but the mTOR inhibitor had a very low response rate. Newer "humanized" antibodies are also being tested to see if they are more effective and if they can minimize the pain produced by the current antibody, which can limit the extent of treatment. Studies are also in preparation to evaluate the use of the GD2 antibody in front-line therapy.

A new synthetic retinoid, fenretinide, which has produced apoptosis rather than differentiation in neuroblastoma cell lines, is also in clinical trials for maintenance therapy. It has been shown to be effective against some neuroblastoma cell lines that are resistant to 13-cis-retinoic acid.

Other avenues of treatment in current phase I and phase II trials include vaccine and antiangiogenic therapy. Vaccines have been developed against the GD2 antigen, but they are in early stages of testing. Inhibition of angiogenesis is another appealing avenue of therapy in this very vascular tumor, particularly once there is minimal residual disease, although efficacy has not yet been established in phase 1 or 2 studies.

Another modality in the treatment of metastatic neuroblastoma is the use of ^{131}I-MIBG (Hutchinson et al., 1992). The finding that the primary tumor and metastatic areas take up this radiotracer suggested the possibility that therapeutic doses can be delivered to the tumor. Preliminary analysis indicates that objective responses do occur in terms of reduction of tumor volume, even in previously heavily treated patients (Howard et al., 2005; Matthay et al., 2007). Significant myelosuppression is seen with dose escalation, however, and stem cell support is required. It has not yet been tested as an "up-front" therapy.

Radiotherapy

Radiotherapy is effective for local control in neuroblastoma, and risk of local relapse can be correlated with the biologic markers. Although irradiation has not provided a benefit in low-stage tumors, it has increased local control in children with advanced stage IV or bulky stage III tumors (Castleberry et al., 1991; Evans et al., 1996; Matthay et al., 1989). A randomized control trial to evaluate the efficacy of local control between radiotherapy alone and surgery has not been performed. Doses of external beam irradiation used have ranged between 15 and 30 Gy, depending on the patient's age, location of the tumor, and extent of residual disease.

Intraoperative radiation therapy has been used for patients with unresectable disease. This technique has the advantage of delivering a higher dose of radiation to the operative field while sparing normal adjacent tissues (Leavey et al., 1997). Although its use has been promoted, it has not been convincingly demonstrated to improve control when compared with external beam irradiation (Haas-Kogan et al., 2000).

Spinal Cord Compression

Extension of tumor into the spinal canal produces symptoms of spinal cord compression in up to 5% of patients presenting with neuroblastoma (DeBernardi et al., 2001), whereas up to 13% of patients have radiographic evidence of extension into the spinal canal (Plantaz et al., 1996). These children have been treated by decompressive laminectomy, radiotherapy, or chemotherapy. Neurologic outcome has been similar by all modalities and, unfortunately, patients presenting with severe motor deficits generally recover little function (DeBernardi et al., 2001; Katzenstein et al., 2001). Because of the delayed complications of scoliosis after laminectomy, current recommendations are to initiate treatment with chemotherapy and reserve laminectomy for children with progressive neurologic deterioration (Katzenstein et al., 2001). Radiotherapy is now generally avoided, because of its adverse effect on growth of the spine.

Key Points: Neuroblastoma

- Neuroblastoma is the most common extracranial solid neoplasm in children.
- Children 18 months of age or younger have a better survival rate than older children. This may be attributed to more favorable biologic parameters in tumors diagnosed at this age.
- Complete surgical resection is curative for low-stage disease.
- *MYCN* amplification, found in 20% of patients with primary tumors, is

associated with tumor progression. This poor prognosis is independent of patient age and tumor stage. Additional biologic markers of poor prognosis have been defined and treatment protocols are currently based on these factors.

Wilms Tumor

Wilms tumor, or nephroblastoma, is the most common primary malignant renal tumor of childhood. It is an embryonal tumor that develops from remnants of immature kidney. Treatment of patients with nephroblastoma has been extensively investigated in a number of large randomized clinical trials in North America and Europe. The focus of the most recently completed trials was on reducing the morbidity of treatment for low-risk patients, reserving more intensive treatment for high-risk patients for whom survival remains poor. This section outlines current recommendations for treatment and reviews the latest developments in the biology of Wilms tumor.

Epidemiology

Wilms tumor accounts for approximately 6% to 7% of all childhood cancers. It is the most common renal tumor of childhood, accounting for 95% of all kidney cancers in children under the age of 15 in the United States (Ali et al., 2012; Howlader et al., 2013). According to the Surveillance, Epidemiology, and End Results (SEER) registry, the average annual age-adjusted incidence rate of Wilms tumor is 8.0 per million (Bernstein et al., 1999; Breslow et al., 1993). More than 80% of cases are diagnosed before 5 years of age, with a median age of 3.5 years. Nevertheless, older children and occasionally even adults can be affected (Ali et al., 2012; Arrigo et al., 1990; Kalapurakal et al., 2004a). The median age at diagnosis is lower in children with bilateral Wilms tumor (Breslow et al., 1993) and those with a syndromic predisposition to Wilms tumor (Kalish et al., 2017). Wilms tumor presents at an earlier age among males with both unilateral and bilateral tumors.

In North America, Wilms tumor is slightly more frequent in females than in males. With regard to ethnicity, the incidence of Wilms tumor is lower in East Asian populations and higher in black populations compared with the incidence reported for North American and European Caucasians (Axt et al., 2011; Breslow et al., 1994; Fukuzawa et al., 2004). The fact that such variations exist more closely associated with race than geography suggests that environmental risk factors likely play a minor etiologic role, certainly in comparison with adult epithelial cancers (Breslow et al., 1993). Black children often have a more advanced stage of disease at presentation, but it is not clear if this is related to tumor biology or reflects delays in diagnosis resulting from impaired access to health care (Axt et al., 2011). Data also exist on the very poor survival outcomes of children in Africa with Wilms tumor; however, as with the data on black children in North America it is still unclear what contribution tumor biology plays relative to other known barriers to care (Paintsil et al., 2015). Several epidemiologic studies have investigated occupational, environmental, and lifestyle factors as risk factors for Wilms tumor. Although some studies have suggested that a number of parental and prenatal exposures may be associated with an increased risk of Wilms tumor, very few have been established conclusively (Breslow et al., 1993; Shrestha et al., 2014).

Biology/Genetics

Children with Wilms tumor have been extensively studied to determine the role of genetic alterations in tumor development (Gadd et al., 2012). We now recognize that the majority of Wilms tumors arise from somatic mutations restricted to tumor tissue and a much smaller percentage originate from germline mutations (Dome and Huff, 2016; Ruteshouser et al., 2008; Scott et al., 2012). It is apparent that several genetic events result in Wilms tumorigenesis and that the Knudson two-hit model of cancer formation does not explain most cases (Knudson and Strong, 1972). In 10% to 15% of individuals with Wilms tumor, the cause is considered to be a germline pathogenic variant or an epigenetic alteration occurring early during embryogenesis (see 11p15-Related Wilms Tumor). These may or may not be associated with a known congenital malformation syndrome or hereditary cancer syndrome. Approximately 1% to 2% of individuals with Wilms tumor have at least one relative also diagnosed with Wilms tumor (familial Wilms tumor); however, although germline variants that are likely pathogenic have been identified in some families, they are still not known for the majority of individuals. The most commonly reported germline genetic and epigenetic variants in individuals with Wilms tumor involve WT1 and the 11p15.5 locus. A growing number of variants in other genes have been reported. In some cases, the estimated of risk of Wilms tumor with these variants is high, but the variant or syndrome is so rare in the general population that only a handful of individuals with Wilms tumor have ever been reported (Dome and Huff, 2016). A number of genes have been identified that play a role in the development of Wilms tumor (Table 53.3).

TABLE 53.3

Gene Mutations in Wilms Tumors

GENE (CHROMOSOME)	FREQUENCY	SOMATIC OR GERMLINE
IGF2 (11p15)	70%	Both
WTX (Xq11)	20%	Somatic only
WT1 (11p13)	20%	Both
CTNNB1 (3p21)	15%	Somatic only
TP53 (17p13)	4% all tumors	Both
	70% anaplastic	

WT1

The first gene mutation described in Wilms tumor was *WT1* with somatic and germ-line mutations noted. **The identification and subsequent cloning of *WT1* resulted from cytogenetic observations of gross deletions at chromosome 11p13 in patients with the WAGR (Wilms tumor, Aniridia, Genital anomalies, mental Retardation) syndrome.** These children were shown to have heterozygous germline deletions at 11p13 (Riccardi et al., 1978). Subsequent molecular analysis of the DNA mapping of this specific region led to the identification of the *WT1* in 1990 (Bonetta et al., 1990; Call et al., 1990). *WT1* mutations are often associated with β-catenin (*CTNNB1*) mutations, defining a specific genetic subset of Wilms tumor (Li et al., 2004; Royer-Pokora et al., 2008). This subset has been called the ideal type I Wilms tumor (Breslow et al., 2006). It is characterized by a stromal predominant favorable histology, intralobar nephrogenic rests, early onset of Wilms tumor, and genitourinary abnormalities in males. Wilms tumors from patients with Wilms tumor-aniridia-urogenital abnormalities-mental retardation (WAGR) and Denys–Drash syndrome (DDS) belong to this subtype of tumors.

Aniridia, found in 1.1% of Wilms tumor patients, arises from deletion of *PAX6*, which lies within approximately 0.6 Mb of *WT1* (Vasilyeva et al., 2017). Aniridia patients with visible (microscopic) chromosomal deletions that include *WT1* were noted to be prone to the development of Wilms tumor (Muto et al., 2002). FISH analysis of aniridia patients has been used to identify submicroscopic deletions of *WT1* and is also a useful predictor of Wilms tumor development (van Heyningen et al., 2007). Wilms tumor will develop in approximately 40% to 70% of aniridia patients with deletions of *WT1*.

Conversely, aniridia patients with normal *WT1* do not develop Wilms tumor (Grenskov et al., 2001; van Heyningen et al., 2007).

The *WT1* gene is important for normal kidney and gonadal development. *WT1* encodes a zinc finger transcription regulating mesenchymal to epithelial transition in kidney development (Dressler, 1995; Pritchard-Jones, 1990). *WT1* is necessary for ureteric bud outgrowth and is also important in nephrogenesis. Targeted mutation of the *WT1* gene in mice results in failure of kidney and gonadal development (Kreidberg et al., 1997). **The Denys-Drash syndrome (DDS) is the specific association of male pseudohermaphroditism, renal mesangial sclerosis, and nephroblastoma** (Drash et al., 1970). The syndrome is caused by point mutations in the zinc-finger DNA binding region of *WT1* (Coppes et al., 1993). More than 90% of DDS patients harbor germline point mutations in only one *WT1* allele (Coppes et al., 1992; Pelletier et al., 1991). Therefore the *WT1* mutation acts dominantly with respect to genitourinary abnormalities. The fact that the phenotype resulting from these heterozygous mutations is far more severe than that resulting from constitutional deletion of one *WT1* allele (i.e., WAGR patients) suggests that the Denys-Drash mutations do not result in inactivation of the WT1 protein, but rather in the production of a dysfunctional *WT1* protein. It is postulated that this abnormally expressed protein alters regulation of transcription and urogenital development. The majority of these patients progress to end-stage renal disease. Nephropathy usually occurs early in life and renal biopsy demonstrates mesangial sclerosis. Some *WT1* mutations can lead to an incomplete DDS phenotype, with varying degrees of genitourinary anomalies, renal pathologies, and penetrance of Wilms tumor (McTaggart et al., 2001). Although XY individuals have been reported most often, the DDS has been reported in genotypic/phenotypic females. WAGR and DDS patients are more likely to have bilateral tumors and are diagnosed at a younger age (Breslow et al., 2003, 2006).

This risk for renal insufficiency in DDS is shared by children with WAGR and children with genitourinary abnormalities, all associated with a *WT1* mutation (Diller et al., 1998). **WAGR patients and those with genitourinary abnormalities have an increased risk of renal failure if they survive into puberty** (Breslow et al., 2000, 2005). Genitourinary anomalies (renal fusion anomalies, cryptorchidism, hypospadias) are present in 4.5% of patients with Wilms tumor (Breslow et al., 1993). The incidence of *WT1* mutations in patients with Wilms tumor not associated with any genitourinary abnormality is approximately 2% (Little et al., 2004). Studies of non-tumoral renal tissue in children with WAGR and DDS have demonstrated smaller glomerular diameters than controls (Dahan et al., 2007). This suggests a specific defect of WT1 function during renal development that leads to subsequent deterioration in renal function with age.

WT1 was originally considered to be a classic tumor suppressor gene, and the loss of both copies or mutations of this gene would lead to Wilms tumor development (Rauscher, 1993). Although this may be the case for some tumors, only 20% of patients with Wilms tumor have a mutation in the germline or in tumor tissue (Diller et al., 1998; Ruteshouser et al., 2008). It is well established that most constitutional cancer syndrome mutations, including *WT1*, are associated with younger age of onset. The median age of onset in children with somatic *WT1* mutations was 14 months. It is postulated that *WT1* mutations are associated with a more rapid progression to Wilms tumor than other molecular abnormalities (Scott et al., 2012).

WTX

Another tumor suppressor gene, *WTX*, is targeted by somatic mutations in up to 30% of cases of Wilms tumor, the most common type of pediatric kidney cancer (Rivera et al., 2007). Most tumors have deletions of the entire WTX gene, but one-third of WTX-mutated Wilms tumors carry truncating mutations or missense mutations. The functional importance of the missense alterations is unclear, because the missense alteration can be present in normal tissue from the same patient, whereas the deletion and truncation mutations are always specific to the tumor. The location of WTX on the X chromosome is of particular interest because it is inactivated by a monoallelic, or “single-hit” event rather than by the classical biallelic inactivation of autosomal tumor suppressor genes. It targets the single X chromosome in males and the active X chromosome in females with tumors and occurs at comparable frequencies in males and females alike. Initially it was reported that tumors caused by *WTX* mutations lack *WT1* mutations. Subsequently, it has been observed that *WTX* mutations occur with equivalent frequency in tumors with or without mutations in *WT1* and *CTNNB1* (Ruteshouser et al., 2008). *WTX*, like *WT1*, appears to play a role in the Wnt/beta-catenin signaling pathway. Mutations in *WT1*, *WTX*, and *CTNNB1* provide the genetic basis for about one-third of Wilms tumors (Bahrami et al., 2018).

11p15

Additional molecular alterations are observed at the chromosome 11p15 locus, which contains a cluster of imprinted genes (Koufos et al., 1989; Mannens et al., 1990). LOH or loss of imprinting (LOI) on 11p15 occurs in up to 70% of tumors (Scott et al., 2012). A WT2 locus has been postulated in 11p15, but so far, the respective gene has not been identified. **This region is known to harbor genes for the Beckwith-Wiedemann syndrome (BWS) and other syndromes with overgrowth features** (Koufos et al., 1989). **These include hemihypertrophy, which may occur alone or as part of the BWS, Perlman, Soto, and the Simpson-Golabi-Behmel syndromes** (Neri et al., 1998; Perlman et al., 1975). Most cases of BWS are sporadic, but up to 15% exhibit heritable characteristics with apparent autosomal dominant inheritance. The BWS critical region on 11p15 includes two domains of imprinted genes located in proximity in band 11p15. Imprinting center region 1 (ICR1) regulates the expression of *IGF2* and *H19*; and center 2 (ICR2), which regulates the *CDKN1C*, *KCNQ10T1*, and *KCNQ1*. These imprinting centers are differentially methylated on the paternal and maternal allele, leading to expression of only one parent-specific allele (Choufani et al., 2013).

Wilms tumor associated with epigenetic alterations in the 11p15 region has been termed the ideal type II Wilms tumor (Breslow et al., 2006). A type II Wilms tumor is characterized by a limited nephrogenic differentiation and a mostly blastemal or epithelial-type histology; patients develop tumors at a later age and have a heavier birth weight. **The risk of nephroblastoma in children with BWS and hemihypertrophy is estimated to be 4% to 10%; 21% of children have bilateral disease** (Beckwith, 1996; Debaun and Tucker, 1998; Porteus et al., 2000). The mean age at diagnosis of Wilms tumor in BWS and hemihypertrophy patients is similar to that of the general Wilms tumor population (Breslow et al., 1993). Adrenocortical neoplasms and hepatoblastoma also occur with increased frequency in BWS. Children with BWS found to have nephromegaly (kidneys greater than or equal to the 95th percentile of age adjusted renal length) are at the greatest risk for the development of Wilms tumor (Debaun et al., 1998). Investigators have been able to correlate genetic changes to identify which BWS patients are at risk for Wilms tumor development (Bliek et al., 2004; Brioude et al., 2013; DeBaun et al., 2002). An increased Wilms tumor risk is observed only in BWS patients with ICR1 gain of methylation and 11p15 uniparental disomy. In contrast, the tumor risk is lower in BWS with ICR2 loss of methylation and CDKN1C mutations.

Familial Wilms Tumor

As noted earlier, 1% to 2% of Wilms tumor patients have a family history of Wilms tumor (Breslow et al., 1996; Ruteshouser and Huff, 2004). Familial cases have an earlier age of onset and an increased frequency of bilateral disease. Two familial Wilms tumor genes have been localized (Ruteshouser and Huff, 2004). FWT1 is located at 17q12-q21 and FWT2 at 19q13.4 (McDonald et al., 1998; Rahman et al., 1996). Penetrance of these genes appears to be moderate, and these genes do not follow the typical tumor suppressor gene pattern of loss of heterozygosity (Strong, 2003).

Other Chromosomal Abnormalities

Mutations of the tumor suppressor gene *TP53* are frequently encountered genetic events in human cancer (Hollstein et al., 1991). *TP53* mutations are detected in 50% to 75% of patients with anaplastic histology Wilms tumor (Bardeesy et al., 1994, Ooms et al., 2016). It has been suggested that a favorable histology tumor may progress to an anaplastic tumor by acquiring a disruption of *TP53* function in a group of selected cells (Natrajan et al., 2007). The *TP53* mutations also have been correlated with advanced stage disease (Malkin et al., 1990; Sredni et al., 2001). A recent report from COG on *TP53* mutations in diffuse anaplastic Wilms tumor noted improved relapse-free survival in those with advanced stage disease who had wild-type *TP53* (Ooms et al., 2016).

Loss of the long arm of chromosome 16 has been found in approximately 20% of Wilms tumors (Maw et al., 1992), suggesting the presence of a gene at 16q involved in the biology of Wilms tumor. Similarly, loss of the short arm of chromosome 1p has been found in approximately 10% of cases (Grundy et al., 1994). **LOH at 1p and 16q are associated with an increased risk of tumor relapse and death** (Grundy et al., 1994, 2005; Wittman et al., 2007). Confirming the utility of LOH of 16q and 1p to predict outcome was one of the major objectives of the fifth National Wilms Tumor Study (NWTS) (see discussion later). LOH of chromosome 11q is noted in approximately 20% of tumors. LOH of 11q is 3 to 4 times more frequent in anaplastic tumors (Wittman et al., 2007). There is a correlation with tumor recurrence and death but only for tumors that lost the entire long arm of chromosome 11. Combined LOH (at 1p and 16q) was used to risk-stratify patients with favorable-histology Wilms tumor (FHWT) on the most recently completed COG renal tumor studies. COG Study AREN 0533 intensified therapy for those stage III and IV FHWT and demonstrated that therapeutic intensification improved EFS and OS (Dix et al., 2015; Fernandez et al., 2018). However, this is of limited clinical importance because only approximately 5% of all FHWT patients have combined LOH.

Gain of 1q has also been identified to be another genetic change associated with outcome (Gratias et al., 2013, 2016; Segers et al., 2013). 1q gain has the potential to be a more clinically significant factor because it is consistently noted in one-fourth of FHWTs. It is important to note that 1q gain and LOH at 1p and 16q are not independent events. LOH at 1p and 16q often arises through chromosomal translocations that also result in 1q gain. After stratification for stage of disease, 1q gain was associated with a significantly increased risk of disease recurrence and worse OS (Gratias et al., 2016). Future studies will likely investigate the ability of 1q gain to be used to risk-stratify patients for therapeutic intensification.

COG investigators have evaluated a large cohort of FHWTs for global gene expression patterns; *WT1*, *CTTNNB1*, and *WTX* mutation; and 11p15 copy number and methylation patterns. They identified five subsets of tumors showing distinct differences in their clinical and pathological features. One unique subset was epithelial Wilms tumor in infants that lacked *WT1*, *CTTNNB1*, and *WTX* mutations and nephrogenic rests, and none had recurrence of tumor. COG investigators hope to use this type of information to develop specific treatment strategies for different subsets of patients based on biology (Gadd et al., 2012; Sredni et al., 2009).

Screening

Screening with serial renal sonograms has been recommended in children at high risk for development of Wilms tumor. Review of most studies suggests that 3 to 4 months is the appropriate screening interval. The frequency of screening does not change as the patient ages; the rate of tumor growth is expected to be the same in older children. Tumors detected by screening will usually be at a lower stage (Choyke et al., 1999; Green et al., 1993; Kalish et al., 2017). No studies have demonstrated that early detection has improved patient survival. Early detection can provide an opportunity for nephron-sparing surgery, because these children are at an increased risk for bilateral disease. The smaller tumors found on screening studies are more amenable to renal-sparing surgery (Romao et al., 2012; Fig. 53.6). A recent report from the American Association for Cancer Research Childhood Cancer Predisposition Workshop recommended that screening be performed when a condition has a Wilms tumor incidence of greater than 1% (Table 53.4; Kalish et al., 2017). Others have recommended screening when the Wilms tumor incidence is greater than 5% (Scott et al., 2006a,b). Although there is emerging evidence of different cancer risks based on genetic or epigenetic subgroups for certain syndromes, and several European countries now use subgroup-specific recommendations for WT screening particularly in BWS, these practices have not yet been adopted in North America (Mussa et al., 2016). Ultrasound surveillance is recommended until 7 years of age. For patients with BWS/IHH, trisomy 18, and SGBS, screening for hepatoblastoma is also required. They need full abdominal ultrasound and simultaneous serum AFP screening every 3 months starting at birth (or at the time of diagnosis) and continuing through the child's fourth birthday.

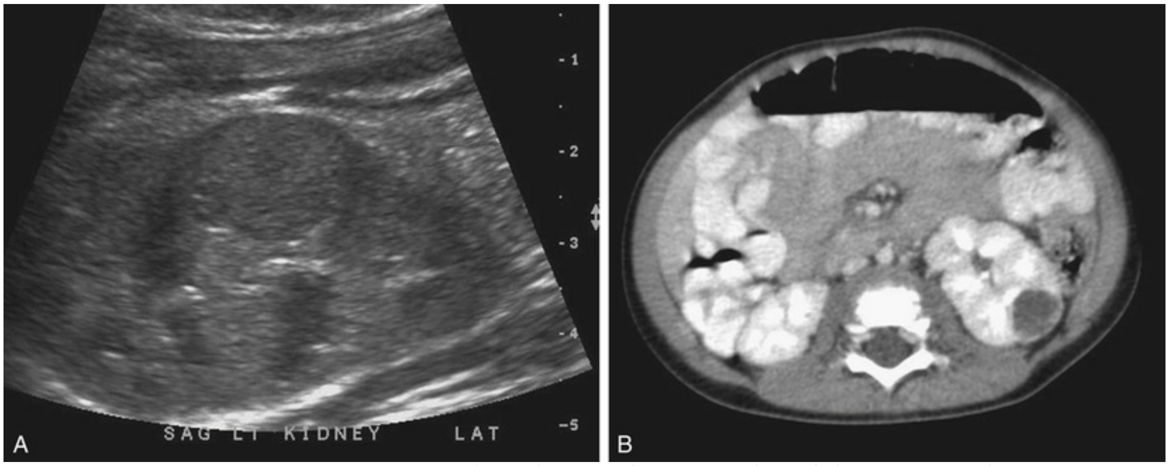

FIG. 53.6 Small renal tumor found on serial screening. (A) Ultrasound shows solid lesion just pushing out from the cortex. (B) CT demonstrates that lesion is amenable to renal-sparing surgery.

TABLE 53.4

Syndromes Associated With Development of Wilms Tumor

SYNDROME	GENES	LOCUS	WILMS TUMOR RISK
HIGH RISK			
WAGR	*WT1*	11p13	50%
Denys-Drash	*WT1*	11p13	50%
Fanconi anemia D1	*BRCA2*	13q12.3	>20%
Perlman	Unknown		>20%
Mosaic variegated aneuploidy	*BUB1B*	15q15	>20%

MODERATE RISK			
Beckwith-Wiedemann	*WT2*	IGF2, H19	5%–10%
Hemihypertrophy	*WT2*	IGF2, H19	5%
Frasier	*WT1*	11p13'	5%–10%
Simpson-Golabi-Behmel	*GPC3*	Xq26	10% (in males)
LOW RISK			
Li-Fraumeni	*p53*	17p13	Low
Neurofibromatosis	*NF1*	17q11	Low
Sotos	*NSD1*	5q35	Low
Trisomy 18	Unknown	18	Low
Bloom	*BLM*	15q26	Low

Screening of the contralateral kidney after nephrectomy for unilateral Wilms tumor is also recommended (D'Angio et al., 1993). Infants younger than 12 months found to have nephrogenic rests (NRs) in the resected kidney are at the greatest risk for metachronous tumors (Coppes et al., 1999). Ultrasound surveillance is performed from time of diagnosis until 5 years of age, with a frequency of every 3 to 4 months.

CT or MRI should be performed if ultrasonography demonstrates a suspicious lesion. Nonmalignant renal lesions—for example, renal cysts—do occur at an increased rate in children with BWS, and recognition of these is important to avoid unnecessary nephrectomy when new lesions are identified on screening ultrasonography (Borer et al., 1999; Choyke et al., 1999).

Pathology

Pathologists have made important contributions to the study of the clinical behavior and biology of Wilms tumor (Beckwith and Palmer, 1978; Gadd et al., 2012, 2017; Perlman et al., 2011; Ravenel et al., 2001; Schmidt and Beckwith, 1995; Vujanic et al., 2002, 2010; Weeks et al., 1987; Zuppan et al., 1991). Wilms tumor is characterized by wide histologic diversity, and thus the classification of these childhood tumors can be difficult. As noted in the discussion earlier, correlation of the pathologic findings with genetic events is improving our understanding of the development of Wilms tumor.

Favorable Histology Wilms Tumor

Wilms tumor usually compresses the adjacent normal renal parenchyma, forming a pseudocapsule composed of compressed, atrophic renal tissues. This intrarenal pseudocapsule can be helpful to distinguish Wilms tumor from NRs and other renal tumors. The texture of the tumors varies depending on the predominant histologic pattern. Many are soft and friable with necrotic or hemorrhagic areas frequently noted. This consistency increases the risk of intraoperative tumor rupture during primary nephrectomy. Most Wilms tumors are unicentric, but 12% are multicentric unilateral tumors (Breslow et al., 1988a). Extrarenal Wilms tumor arising in the retroperitoneum and elsewhere are rare and are thought to arise from displaced metanephric elements or mesonephric remnants. Wilms tumor is derived from primitive metanephric blastema (Beckwith and Palmer, 1978). In addition to expressing a variety of cell types found in a normal developing kidney, Wilms tumor often contains tissues such as skeletal muscle, cartilage, and squamous epithelium. These heterotopic cell types likely reflect the primitive developmental potential of metanephric blastema that is not expressed in normal nephrogenesis. **"Classic" Wilms tumor is characterized by islands of compact undifferentiated *blastema* and the presence of variable *epithelial* differentiation in the form of embryonic tubules, rosettes, and glomeruloid structures separated by a significant *stromal* component** (Fig. 53.7). The proportion of each of these components varies from infrequent to abundant within and among individual tumors. However, some Wilms tumors are not triphasic but have only biphasic or even monomorphous patterns, and the latter can present diagnostic difficulty (Schmidt and Beckwith, 1995). **Wilms tumors with predominantly epithelial differentiation have a low degree of aggressiveness, and the majority are stage I tumors** (Beckwith et al., 1996; Gadd et al., 2012; Vujanic and Sandstedt, 2010)**. However, these tumors may be more resistant to therapy if they are seen initially as advanced stage disease.**

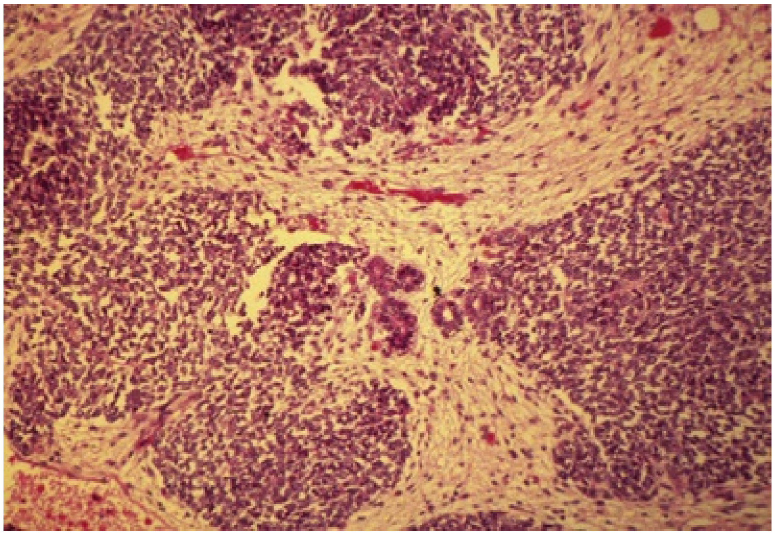

FIG. 53.7 Typical Wilms tumor with blastemal, epithelial, and stromal components.

Anaplastic Wilms Tumor

Identification of tumors with unfavorable histologic features such as anaplasia was an important milestone accomplished by the inclusion of the central pathological review of the National Wilms Tumor Study Group protocols (Beckwith and Palmer, 1978; Bonadio et al., 1985; Zuppan et al., 1991). It has allowed progressive use of adjuvant therapies in the sequential studies based on the risk and response of the various pathological tumor types. Anaplasia is characterized by the presence of three abnormalities: nuclear enlargement to three or more times the diameter of the adjacent cells, hyperchromasia of enlarged nuclei, and abnormal mitotic figures. Anaplasia is rarely seen in tumors of patients younger than 2 years of age at diagnosis (incidence about 2%), but its presence increases to a relatively stable incidence of about 13% in those older than 5 years of age (Bonadio et al., 1985; Green et al., 1994). **Anaplasia is associated with resistance to chemotherapy**. **The presence of anaplasia has clearly been demonstrated to carry a poor prognosis even when the tumor is apparently confined to the kidney, stage I** (Dome et al., 2006). Anaplasia has been further divided into focal and diffuse patterns to reflect further the different prognosis of anaplasia that is present throughout the kidney or in an extrarenal location (Faria et al., 1996). The later age at diagnosis and the general absence of anaplasia from nephrogenic rests suggests that anaplasia develops from Wilms tumor cells that acquire additional genetic lesions (Williams et al., 2011). As mentioned earlier, approximately 50% of anaplastic Wilms tumors harbor *TP53* mutations.

Pathology After Preoperative Chemotherapy

The International Society of Paediatric Oncology (SIOP) studies have made some important observations on the histology of Wilms tumor after preoperative chemotherapy. They have performed an assessment of the tumor response after preoperative chemotherapy in terms of tumor volume and histology. The relative proportions of histologic subtypes of WT differ following preoperative chemotherapy when compared with those reported after primary surgical resection (Weirich et al., 2001). **Stromal and epithelial predominant tumors are found more often after chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised** (Verschuur et al., 2010). The proportion of blastemal predominant tumors is decreased after chemotherapy, indicating some response of this tumor type to the preoperative chemotherapy. **However, patients with blastemal predominant tumors after chemotherapy have a high rate of relapse** (Reinhard et al., 2004b). Tumor progression during therapy occurred in 5% of patients enrolled in SIOP 93-01 (Ora et al., 2007). These patients were documented to have decreased OS.

As an embryonal tumor, nephroblastoma may differentiate into more mature mesenchymal tissue types, such as skeletal muscle, after chemotherapy. Chemotherapy and radiation may induce cytodifferentiation of Wilms tumor cells or select for the survival of less mitotically active cells. In follow-up biopsies, the presence of rhabdomyomatous differentiation can confound the histologic diagnosis. Furthermore, these differentiated tumors appear to be more resistant to chemotherapy, thus surgical excision is considered the treatment of choice (Seifert et al., 2012).

SIOP classifies tumors with complete tumor necrosis after preoperative chemotherapy as “low risk.” **The blastemal element commonly responds very dramatically to chemotherapy. The degree of tumor necrosis after chemotherapy has a positive correlation with the proportion of blastemal component and a negative correlation with proportion of epithelial component in pre-chemotherapy biopsy samples** (Taskinen et al., 2017)**. Unfortunately, if not responsive to therapy and there is blastemal predominance in residual tumor specimens after pre-surgical chemotherapy, this predicts worse survival outcomes** (Reinhard et al., 2004b). Children with stage I “low-risk” tumors after post-chemotherapy nephrectomy receive no further chemotherapy (Boccon-Gibod et al., 2000). Tumors with diffuse anaplasia and blastemal predominance after chemotherapy are classified as “high risk.” SIOP “intermediate risk” tumors comprise all other histologies.

Nephrogenic Rests

More than one-third of kidneys resected for Wilms tumor (regardless of those receiving preoperative chemotherapy or not) contain precursor lesions known as NRs (Beckwith, 1993; Beckwith et al., 1990; Vujanić et al., 2017). Nephrogenic rests have a varied natural history and most do not form Wilms tumor. A rest can undergo maturation, sclerosis, involution, or complete disappearance. NRs have also been detected in 1% of kidneys in infants on postmortem examination; a much higher incidence than that of Wilms tumor. Therefore most apparently undergo involution (Beckwith, 1998). It has been recently postulated that epigenetic changes and relative methylation affect Wilms tumor evolution from its precursor NRs, which may be useful to differentiate between these tissues and potentially predict which NRs will become Wilms tumors (Charlton et al., 2015).

NRs can be separated into two fundamentally distinct categories, *perilobar nephrogenic rests* (PLNRs) and *intralobar nephrogenic rests* (ILNRs) (Beckwith et al., 1990). These two types of NRs are distinguished by their location within the renal lobe. Relative position within the lobe is a direct reflection of the chronology of the embryologic development of the kidney. **PLNRs are found only in the lobar periphery, which is elaborated late in embryogenesis, whereas ILNRs are found anywhere within the lobe, as well as the renal sinus and the wall of the pelvicaliceal system.** Therefore ILNRs are generally believed to be the result of earlier gestational aberrations (Beckwith, 1998). ILNRs are commonly stroma rich and intermingle with the adjacent renal parenchyma. PLNRs are usually subcortical, sharply demarcated, and contain predominantly blastema and tubules. Of particular interest is the observation that PLNRs are usually found in children with BWS, linked to 11p15, whereas ILNRs are typically seen in children with aniridia, WAGR, and DDS or other features associated with *WT1*. The age at diagnosis is lower for Wilms tumor associated with *WT1* mutations and those arising in association with ILNR. These tumors have a stromal-predominant histology with varying degrees of rhabdomyogenesis (Fukuzawa et al., 2008).

Multiple rests in one kidney usually implies that NRs are present in the other kidney (Beckwith et al. 1990). **Children younger than 12 months of age diagnosed with Wilms tumor who also have NRs, in particular PLNRs, have**

a markedly increased risk of developing contralateral disease and require frequent and regular surveillance for several years (Coppes et al., 1999). Surveillance is also recommended for those diagnosed after 12 months of age who have NRs (D'Angio et al., 1993). The occurrence of metachronous Wilms tumor in patients previously treated with conventional chemotherapeutic regimens suggests that nephrogenic rests are not always eradicated.

NRs display a spectrum of appearances. Hyperplastic NRs can produce a renal mass that can be mistaken for a small Wilms tumor (Beckwith, 1998). Incisional biopsy of a hyperplastic rest is of little value in distinguishing this lesion from a Wilms tumor, unless the interface between the rest and normal kidney is included. Wilms tumor has a pseudocapsule at the interface with the normal parenchyma compressing the normal elements. The appearance of the lesion can provide some help in distinguishing between NR and Wilms tumor. The Wilms tumor will have a spheric shape, whereas hyperplasic rests retain the appearance of the original rest and are more elliptical or lenticular in shape. MRI may be of some value in distinguishing between the two lesions, but this must be confirmed prospectively in large numbers of patients (Hoffer, 2005; Rohrschneider et al., 1998).

Nephroblastomatosis refers to the presence of multiple nephrogenic rests. Diffuse overgrowth of PLNRs may produce a thick rind that enlarges the kidney but preserves its original shape (Fig. 53.8). Patients with nephroblastomatosis are prone to Wilms tumor development, and bilateral lesions are common. Perlman et al. (2005) have reviewed 52 cases of diffuse hyperplastic perilobar nephrogenic rests reported to the National Wilms Tumor Study Group (NWTSG) pathology center. Wilms tumor developed in 23 patients at a median of 30 months. Of children receiving adjuvant therapy at diagnosis, 17/33 (52%) developed a Wilms tumor. There was an increased incidence of anaplasia noted in tumors that developed after chemotherapy in patients with nephroblastomatosis (Perlman et al., 2005).

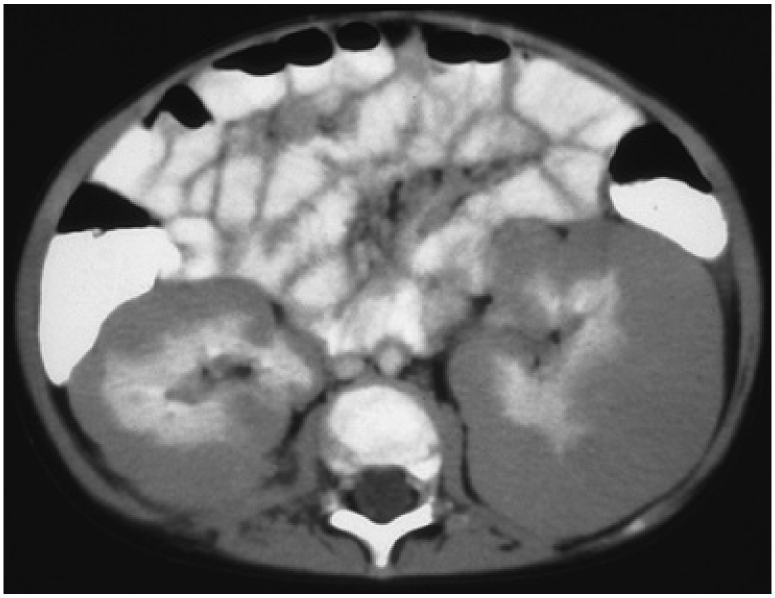

FIG. 53.8 Typical appearance of diffuse hyperplastic perilobar nephrogenic rest with thick rind compressing the normal renal tissue centrally.

Preoperative Evaluation and Staging

The majority of children (>85%) are symptomatic at presentation with either an abdominal mass, abdominal pain or hematuria (Pritchard-Jones et al., 2016). Less commonly an asymptomatic abdominal mass is discovered incidentally by a family member or primary care physician. A small percentage of tumors are diagnosed by screening. A higher proportion of stage I and II tumors (72.7%) are noted in those who are asymptomatic at diagnosis compared with those who are symptomatic (52.9%).

The mass may be extremely large relative to the size of the child and is not necessarily confined to one side. Approximately 20% of children with Wilms tumor have hematuria at diagnosis, and 25% will have hypertension at diagnosis that can be caused by elevated plasma renin levels (Maas et al., 2007). Gross hematuria warrants further evaluation including a cystoscopy and retrograde pyelogram at the time of nephrectomy to rule out tumor extension into the collecting system (Ritchey et al., 2008). Other symptoms include fever, anorexia, and weight loss in 10% of patients. Rarely, children may have acute abdominal pain from tumor rupture into the peritoneal cavity or bleeding within the tumor. There is limited evidence that patterns of diagnosis may differ by medical specialty and that delays in diagnosis can adversely affect survival outcomes

(Pritchard-Jones et al., 2016).

Compression or invasion of adjacent structures may result in an atypical presentation. A persistent varicocele in the supine position or hepatomegaly may be reflective of inferior vena cava (IVC) obstruction from tumor thrombus. Atrial thrombus may manifest as hypertension or congestive heart failure. Such symptoms are found in less than 10% of patients with intracaval or atrial tumor extension (Ritchey et al., 1988; Shamberger et al., 2001). During the physical examination, it is important to assess for signs of associated Wilms tumor syndromes such as aniridia, hemihypertrophy, and genitourinary anomalies.

Emergent operation is not necessary unless there is evidence of active bleeding or tumor rupture. The preoperative laboratory evaluation of a child with an abdominal mass should include a complete blood count, liver enzymes, and serum electrolytes, including blood urea nitrogen, creatinine, and calcium. Because as many as 8% of newly diagnosed patients with Wilms tumor will have acquired von Willebrand disease, coagulation studies should be considered (Baxter et al., 2009). This includes prothrombin time and partial thromboplastin time, which may be normal in the presence of von Willebrand disease. This defect can generally be corrected preoperatively with the administration of 1-desamino-8-d-arginine-vasopressin (DDAVP) but may require IVIG or plasmapheresis (Callaghan et al., 2013). Generally, this acquired defect and coagulopathy will be reversed with surgical removal of the tumor or with preoperative chemotherapy (Baxter et al., 2009; Blanchette and Coppes 2009).

Imaging

All solid renal tumors of childhood have some common radiographic features (Miniati et al., 2008; Smets and de Kraker, 2010). Therefore Wilms tumors cannot be reliably distinguished from other renal tumors (e.g., renal cell carcinoma [RCC], or clear cell sarcoma of the kidney [CCSK]). In the SIOP-9 study, 5.4% of patients in whom preoperative chemotherapy for Wilms tumor was commenced before diagnostic biopsy were found on nephrectomy to have renal malignancies other than Wilms tumor or benign renal conditions (Tournade et al., 2001). In the United Kingdom Children's Cancer Study Group (UKCCSG), 12% of renal tumors clinically and radiographically consistent with Wilms tumor were found to have some other diagnosis on biopsy (Vujanic et al., 2003). Other clinical parameters can provide some clues to the diagnosis. The development of a renal tumor in a child known to have aniridia, hemihypertrophy, or other syndromes associated with an increased incidence of nephroblastoma is most likely to be a Wilms tumor. Bilateral or multicentric tumors are more typical of Wilms tumor, but renal lymphoma can manifest in this fashion. Congenital mesoblastic nephroma (CMN) is the most likely diagnosis in a neonate with a renal mass. However, favorable-histology (FH) Wilms tumor and rhabdoid tumor of the kidney (RTK) can also manifest in the first few months of life (LeClair et al., 2005; Ritchey et al., 1995). The renal origin of the mass is usually apparent on CT, but it can be mistaken for neuroblastoma.

The clinical presentation—that is, as abdominal pain with tumor rupture—can create confusion regarding the preoperative diagnosis. In 2.5% of NWTS-3 patients, there was an erroneous diagnosis before surgical exploration (Ritchey et al., 1992). Most of these children did not have any preoperative imaging studies performed, and this group of patients had an increased incidence of surgical complications. This emphasizes that defining the exact histology is not as important as establishing that the child has a solid renal tumor, allowing the surgeon to plan for a major cancer operation. These events are now rare with modern imaging and the almost universal use of CT and MRI for preoperative evaluation.

Ultrasonography is recommended as first-line imaging in children with an abdominal mass. This demonstrates the solid nature of the lesion, and it can also help triage appropriate subsequent imaging such as chest CT at the same time as abdominal cross-sectional imaging and avoid unnecessary scans such as a noncontrasted CT abdomen. Doppler ultrasonography may be able to exclude intracaval tumor extension that occurs in 4% of Wilms tumor patients (Ritchey et al., 1988; Shamberger et al., 2001). However, properly phased CT has been shown to more reliably identify all clinically significant extension of tumor into the IVC when compared with ultrasonography (Khanna et al., 2012).

All patients should undergo either CT of the abdomen and pelvis with oral and intravenous contrast or MRI of the abdomen and pelvis with gadolinium. MRI avoids radiation but typically requires anesthesia or sedation in young children. These imaging modalities can further define the extent of the lesion (Fig. 53.9; Hoffer, 2005; McDonald et al., 2012; Schenk et al., 2008). This allows improved preoperative planning by evaluating for extrarenal spread of disease, the relationship of the tumor to adjacent visceral structures, and the presence of synchronous tumors in the contralateral kidney. **Routine exploration of the contralateral kidney at the time of nephrectomy is not necessary when preoperative imaging with CT or MRI demonstrates a**

normal contralateral kidney (Ritchey et al., 2005).

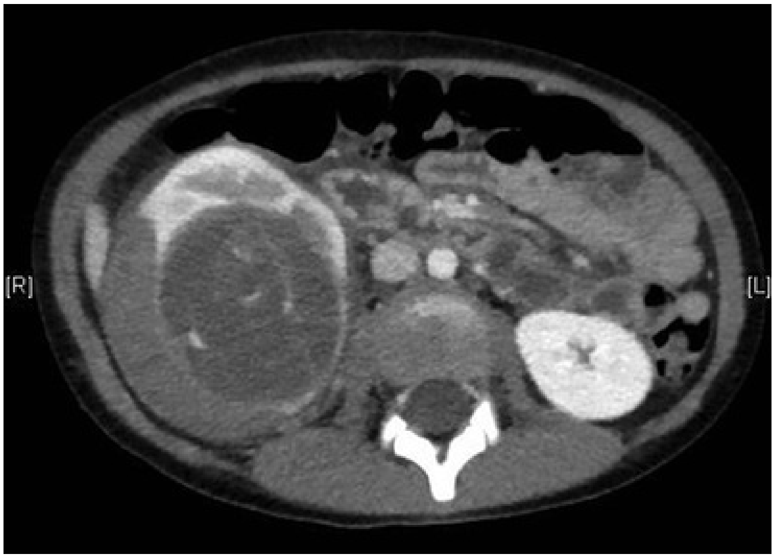

FIG. 53.9 CT scan of a Wilms tumor that demonstrates preoperative rupture with perirenal hemorrhage.

The role of imaging studies in renal tumor staging continues to be defined. The COG found that CT has moderate specificity but poor sensitivity in the detection of preoperative tumor rupture (Khanna et al., 2013). Ascites beyond the cul-de-sac was most strongly associated with tumor rupture. If the preoperative imaging could accurately detect local extension of tumor beyond the renal capsule or into regional lymph nodes, it would obviate concerns regarding staging in patients treated with preoperative therapy. The local tumor burden (e.g., regional lymph node involvement) determines the intensity of the chemotherapy regimen and whether a child receives abdominal irradiation. Regional adenopathy can be identified on CT or MRI, but enlarged retroperitoneal benign lymph nodes are common in children, and correlation between pathologic findings and lymph node evaluation at surgical exploration in Wilms tumor patients has found significant false-positive and false-negative error rates (Lubahn et al., 2012; Othersen et al., 1990). Positron emission tomography (PET) has not been shown to have any advantages over conventional imaging modalities in preoperative assessment of Wilms tumor (Misch et al., 2008). Detection of extrarenal tumor extension into the perirenal fat and into adjacent structures is also problematic. Therefore determination of inoperability should be made at surgical exploration.

The lung is the most common site of distant metastasis in children with

Wilms tumor. Preoperative chest CT with or without contrast is performed to rule out pulmonary metastases. The clinical significance of lung nodules detected on CT scan alone is controversial (Green, 2016; Grundy et al., 2012; Meisel et al., 1999; Owens et al., 2002; Smets et al., 2012). CT will clearly detect more lesions than a standard chest radiograph, but not all of these lesions represent metastases (Ehrlich et al., 2006). Some reports have suggested that treatment of such patients with dactinomycin (actinomycin D [AMD]) and vincristine (VCR) is sufficient without the need for DOX or pulmonary radiation (Grundy et al., 2012; Smets et al., 2012). Others have found an increased risk of pulmonary relapse if more intensive treatment is not given (Owens et al., 2002). The most recent round of renal tumor studies from COG prospectively investigated this issue and found no statistical significant decrease in EFS or OS in children with favorable histology Wilms tumor who lacked LOH at 1p and 16q and who had complete resolution of their lung nodules after 6 weeks of VCR, AMD, and doxorubicin and thus then omitted lung radiation (Dix et al., 2014).

Imaging surveillance after treatment of the primary tumor is recommended to detect tumor recurrence. COG studies advocate for periodic chest CT and either CT or MRI of the abdomen. However, some have begun to question the value of these studies and whether they will detect relapse early enough to improve survival (McHugh and Roebuck, 2014). Many patients will have clinical symptoms related to relapse before imaging detection. Omitting even the pelvic portion of the abdominal CT can significantly reduce the radiation exposure without compromising detection of relapse (Kaste et al., 2013; Mirza et al., 2015).

CCSK and rhabdoid tumor of the kidney (RTK) have a propensity to metastasize to the skeleton (D'Angio et al., 1993; Seibel et al., 2018). Bone scans are recommended after the histologic diagnosis is confirmed (Feusner et al., 1990). Cranial CT or MRI is performed on all children with CCSK or with RTK, because both are associated with intracranial metastases (Gooskens et al., 2014; Tomlinson et al., 2005; Weeks et al., 1989).

Staging

The most important determinants of outcome in children with Wilms tumor are the histopathology and tumor stage. Accurate staging of Wilms tumor allows treatment results to be evaluated and enables universal comparisons of outcomes. The current staging system used by the COG (Table 53.5) is based primarily on the surgical and histopathological findings. Examination for extension through the capsule, residual disease, vascular involvement, and lymph node involvement are essential to properly assess the extent of the tumor at presentation.

TABLE 53.5

Staging System of the Childrens Oncology Group

STAGE	
I	Tumor confined to the kidney and completely resected. The renal capsule is intact and the tumor was not ruptured prior to removal. No renal sinus extension. There is no residual tumor.
II	Extracapsular penetration but is completely resected. Renal sinus extension or extrarenal vessels may contain tumor thrombus or be infiltrated by tumor.
III	Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, any tumor spillage, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed.
IV	Hematogenous metastases to lung, liver, bone, brain, etc.
V	Bilateral renal involvement at diagnosis.

Stage I tumors are limited to the kidney and completely resected. However, evidence for tumor extension can be subtle. Tumor invasion of blood and lymphatic vessels in the renal sinus is the first sign of spread outside the kidney in stage II tumors (Weeks et al., 1987). Penetration through the renal capsule is the next most common finding of extrarenal spread. Clear demonstration of tumor cells in the perirenal fat is required to document capsular penetration. **Any tumor spill leads to a stage III designation because of the increased risk for local tumor recurrence** (Ehrlich et al., 2013; Shamberger et al., 1999). On the COG biology and banking study AREN 03B2, the distribution by stage for patients with FHWT tumors was stage I, 19%; stage II, 20%; stage III, 35%; stage IV, 18%; and stage V, 8% (Mullen et al., 2014). Patients with anaplastic tumors are more likely to present with stage III or IV disease than those with FHWT tumors (Dome et al., 2006).

Prognostic Factors

As the treatment regimens for children with Wilms tumor have become more effective, the ability of retrospectively determined prognostic factors to predict outcomes is diminished. Traditional staging factors (e.g., tumor size, histology, and lymph node metastases) relied upon in the past to predict risk for tumor progression or relapse are now less able to stratify FH patients for treatment. Clinical cancer trials incorporate biologic factors that predict tumor behavior to stratify patients for treatment.

Chromosomal Abnormalities.

As noted earlier, LOH for a portion of chromosome 16q and/or 1p has been noted in 20% of Wilms tumors. This is associated with an increased risk for relapse (Grundy et al., 1994, 2005; Messahel et al., 2009; Wittman et al., 2007). This difference in outcome is independent of histology and stage. NWTS-5 patients with stage I or II FH tumors with LOH of either 1p or 16q had an increased risk of relapse and death in comparison with patients lacking LOH at either locus (Grundy et al., 2005). The risks of relapse and death for patients with stage III or IV FH tumors were increased only with LOH for both regions.

Patients enrolled in the recently published COG renal tumor protocols were selected for more intensive treatment if the tumor demonstrated LOH for 1p and 16q. Compared with historical controls, they found that intensification of treatment improved EFS for stage III FHWT displaying LOH of 16q and 1p (Dix et al., 2015). Treatment was likewise intensified for stage I and II patients, with DOX added to VCR/ACT-D, although this did not significantly affect outcome.

As mentioned earlier, gain of 1q has also been identified to be a related genetic change associated with oncologic outcome (Gratias et al., 2013, 2016; Segers et al., 2013). Future studies will likely expand the investigative thread from the prior generation of COG renal tumor studies to look at treatment intensification for those with FHWT and gain of 1q because only approximately 5% of FHWT will have combined LOH, whereas at least 25% will have gain of 1q.

A number of other markers have been evaluated to predict tumor recurrence including several immunohistochemical markers. It appears that most of the markers that are predictive of tumor progression are found in the blastemal component of the tumor (Ghanem et al., 2013; Routh et al., 2013). These markers will have to be evaluated in larger numbers of patients to determine their usefulness for risk stratification.

Treatment

Surgical Considerations

The initial therapy for most children with Wilms tumor is radical nephrectomy. Nephrectomy is generally performed via a transperitoneal approach. The surgeon is responsible for determining the extent of tumor. Accurate staging is essential for the subsequent determination of the need for radiation therapy and the appropriate chemotherapy regimen. Thorough exploration of the abdominal cavity is necessary to exclude local tumor extension, liver and nodal metastases, or peritoneal seeding. Exploration of the contralateral kidney is no longer mandated before nephrectomy if the preoperative CT or MRI demonstrates a normal kidney (Ritchey et al., 2005). The renal vein and IVC are palpated to exclude intravascular tumor extension before vessel ligation. Wilms tumor extends into the IVC in approximately 6% of cases and may be clinically asymptomatic in more than 50% (Ritchey et al., 1988; Shamberger et al., 2001). The adrenal gland can be spared without increasing the risk for tumor spill or recurrence if it is not in proximity to the tumor (Kieran et al., 2013a). **Selective sampling of regional lymph nodes is an essential component of local tumor staging. Formal retroperitoneal lymph node dissection is not mandated** (Othersen et al., 1990; Shamberger et al., 1999). En bloc resection yields a lower rate of positive lymph nodes compared with separate sampling (Stewart and Bruny, 2015). In a review of NWTS-4 and -5 patients, 12.5% of patients did not have lymph node sampling performed (Kieran et al., 2012). The likelihood of having a positive lymph nodes is greater when more lymph nodes were sampled, emphasizing the importance of the surgeon and surgical quality in accurately staging Wilms tumor (Kieran et al., 2012; Saltzman et al., 2018). Future studies will likely mandate more specific nodal sampling patterns to standardize surgical staging across institutions and individual surgeons.

The other major responsibility when performing a nephrectomy for Wilms tumor is complete removal of the tumor without contamination of the operative field. Gentle handling of the tumor throughout the procedure is mandatory to avoid tumor spillage. A COG study reported intraoperative tumor spillage in 9.7% of patients undergoing primary nephrectomy (Gow et al., 2013). Multivariate analysis demonstrated that spillage was more common with right-sided tumors and larger tumors. Avoiding tumor spillage has a real impact on patient outcomes because these patients have an increase in local abdominal relapse (Shamberger et al., 1999). **Shamberger et al.** (1999) **identified risk factors for local tumor recurrence as tumor spillage, unfavorable histology, incomplete tumor removal, and absence of any lymph node sampling**. This study included stage II and III disease. The risk of recurrence was highest in those patients with stage II disease. More recent COG studies have treated all spill patients as stage III. Review of these patients shows that the greatest risk of recurrence in stage III patients are positive lymph nodes, combined LOH, or residual disease (Ehrlich et al., 2013; Fernandez et al., 2018). Tumor spillage was not predictive of recurrence likely resulting from the increased therapy currently given to these patients.

There have been several reports of laparoscopic or robotic nephrectomy for Wilms tumor. This is usually done in conjunction with preoperative chemotherapy and is likely more feasible after the tumor is reduced in size (Duarte et al., 2014; Romao et al., 2014; Varlet et al., 2014; Warmann et al., 2014). Experience with open nephrectomy after chemotherapy has shown that these tumors are less prone to tumor spillage (Powis et al., 2013). Although pre-chemotherapy laparoscopic nephrectomy has been reported, many more cases will have to be performed to determine if there is an increased risk of tumor spillage, residual disease, or surgical complications (Barber et al., 2009; Cost et al., 2015).

Removing a large renal tumor in a small child is associated with some morbidity. NWTS-4 patients undergoing primary nephrectomy had an 11% incidence of surgical complications (Ritchey et al., 1999). The most common complications encountered are hemorrhage and small bowel obstruction (Ritchey et al., 1992, 1993a, 1999). Factors that have been associated with an increased risk for surgical complications are higher tumor stage, tumor size greater than 10 cm, incorrect preoperative diagnosis, thoracoabdominal incision, intracaval tumor extension, and resection of other visceral organs.

Preoperative chemotherapy may influence surgical complication rates by producing tumor shrinkage. A report from the UKCCSG compared the complication rate for patients undergoing immediate nephrectomy compared with delayed nephrectomy performed after 6 weeks of chemotherapy (Powis et al., 2013). They found significantly fewer complications in those undergoing delayed nephrectomy (1% vs. 5.8%). They also noted a much higher rate of tumor rupture/spill in those undergoing immediate nephrectomy (14.6% vs. 0). This is similar to the rate of intraoperative tumor spill after immediate nephrectomy reported by the COG (Gow et al., 2013).

Cooperative Group Trials

Multiple randomized clinical trials have been conducted by the NWTSG, COG, SIOP, and the UKCCSG to determine the appropriate role for each of the therapeutic modalities available. Patients are stratified into different treatment groups based on stage and pathology. The goals of these trials are to decrease the intensity of therapy for most patients in an effort to prevent late sequelae of treatment while maintaining excellent OS.

National Wilms Tumor Study Group.

The NWTSG was formed in 1969 to study Wilms tumor. The early NWTSG studies, NWTS-1 (1969–1973) and NWTS-2 (1974–1978), showed that the combination of VCR and AMD was more effective than the use of either drug alone. The addition of doxorubicin (DOX) was found to improve survival for stage III and IV patients, and postoperative flank irradiation was unnecessary for stage I patients (D'Angio et al., 1976, 1981). **A major achievement of the early trials was identification of prognostic factors that allowed stratification of patients into high-risk and low-risk treatment groups. Patients with positive lymph nodes and diffuse tumor spill were found to be at increased risk of abdominal relapse and therefore considered stage III and given postoperative irradiation. One of the most important findings was the identification of the unfavorable histologic features that have a very adverse impact on survival.**

NWTS-3 (1979–1986) demonstrated that stage I and II patients could be treated with 18 weeks of AMD and VCR without irradiation (D'Angio et al., 1989). For stage III FH patients, 10.8 Gy of abdominal irradiation was shown to be as effective as 20 Gy in preventing abdominal relapse if DOX was added to VCR and AMD. NWTS-4 (1987–1994) proved that treatment durations of 6 months produced comparable outcomes to 15 months of therapy for patients with stages II to IV/FH tumors (Green et al., 1998). The NWTSG has assessed the impact of postoperative irradiation on flank recurrence and survival (Breslow et al., 2006; Green et al., 2014; Kalapurakal et al., 2010). The investigators found that abdominal recurrence rates after tumor spillage were significantly higher among patients treated with two- or three-drug chemotherapy without RT. Irradiation with 10 Gy appeared to be successful in reducing tumor recurrence rates after tumor spillage, and 20 Gy even more so. Although radiation did decrease the incidence of flank recurrence, there was only an increase in OS for stage II patients with tumor spillage. This was attributed to a lower post-recurrence mortality in unirradiated patients. The overall risk for relapse is low in stage II FH with spillage; the risks of late effects of intensified treatment must be weighed against benefit of decreased relapse (Green et al., 2014).

NWTS-5 (1995–2003) was a single-arm therapeutic trial. One of the major aims of the trial was to confirm the utility of LOH for chromosomes 16q and 1p to predict increased risk of tumor relapse and death (Grundy et al., 2005). Another objective was to evaluate the efficacy of treatment regimens for anaplastic histology Wilms tumor. Stage I patients with anaplastic tumors were treated with AMD and VCR, but this resulted in a low 4-year EFS of 69.5% (Dome et al., 2006). A new intensified chemotherapy regimen used for patients with stage II to IV diffuse anaplasia did not result in an improved survival.

In NWTS-5, children less than 2 years of age with stage I FH tumors weighing less than 550 g were defined as very low-risk Wilms tumors (VLRWT) did not receive chemotherapy after nephrectomy. This portion of the study was closed early when the number of tumor relapses exceeded the limit allowed by the design of the study (Green et al., 2001a). A long-term review of this cohort was completed comparing the outcomes to similar patients treated with postoperative AMD and VCR (Shamberger et al., 2010). The 5-year EFS for surgery alone was 84% compared with 97% for the treated group, but the 5-year OS was equivalent between the two groups at 98% and 99%, respectively ($P = 0.70$). There is a trade-off between more intensive therapy and its potential long-term sequelae required for the 16% of children who relapse versus the avoidance of any postoperative chemotherapy in the majority. As noted earlier, COG investigators hope to use biologic prognostic factors to select patients who do not require adjuvant therapy. All VLRWT registered on NWTS-5 who did not receive adjuvant chemotherapy were analyzed for LOH at 11p15 and for *WT1* mutation. LOH, as determined by 11p15 methylation analysis, was significantly associated with relapse in VLRWT as were *WT1* abnormalities (Perlman et al., 2011). If these results are validated in an independent cohort of patients, it would be worthwhile to conduct a clinical trial that uses molecular genetic factors rather than the arbitrarily defined clinical factors of patient age and tumor weight to identify patients with stage I FHWT who do not require adjuvant therapy. It is anticipated that such a trial would expand the number of patients who would be candidates to be treated with surgery only.

Children's Oncology Group.

The first generation of COG studies (2006–2013) grouped patients by risk for recurrence (very low, low, standard, and high). The COG again examined the role of surgery-only treatment for patients with stage I FHWT in which the tumor and kidney weighed less than 550 g and patient's age was less than 2 years. This further demonstrated the success in a surgery-only approach for those with very low risk FHWT. The 4-year EFS was 89.7% and OS was 100% (Fernandez et al., 2017). This will likely prompt future study of expanding those approaches offered surgery-only.

Children with stage I or II FHWT and LOH of 1p and 16q were treated with VCR, AMD, and DOX without radiotherapy. Patients with stage III FHWT disease without LOH of 1p and 16q were treated with VCR, AMD, and DOX and irradiation of the flank or abdomen. These risk-stratified stage III patients enjoyed an excellent outcome with 4-year EFS of 88% and OS of 97% (Fernandez et al., 2018). The COG evaluated a response-based approach for management of children with pulmonary metastases. Those with resolution of the pulmonary lesions on chest CT after 6 weeks of chemotherapy were continued on treatment with VCR, AMD, and DOX. These patients who were termed “rapid complete responders” had a 4-year EFS of 79.5% and OS of 96.1% that was not statistically inferior to historical standards; this suggests that these risk-adapted patients may be able to avoid lung radiation (Dix et al., 2018). Patients who did not have resolution of the pulmonary lesions by week 6 received more intensive chemotherapy and pulmonary irradiation. These patients were termed “slow incomplete responders” and intensification to regimen M led to an improved outcome with 4-year EFS of 88.5% and OS of 95.4% (Dix et al., 2018).

A specific study was focused on those with “high-risk” renal tumors. Children with stage I to III focal anaplastic histology Wilms tumor (AHWT) and stage I diffuse AHWT were treated with AMD, VCR, DOX, and abdominal irradiation. Patients with stage II, III, or IV (no measurable disease) diffuse AHWT, stage IV focal AHWT, stage IV clear cell sarcoma, and stage I to III malignant rhabdoid tumor were treated with a new chemotherapy regimen to try to improve OS. Publication of these trial data is still pending.

International Society of Paediatric Oncology.

In the randomized clinical trials conducted by SIOP, preoperative therapy is given before surgery. This approach usually results in tumor shrinkage (Fig. 53.10), reducing the risk of intraoperative rupture or spill (Lemerle et al., 1976). A greater number of patients have “post-chemotherapy stage I” tumors resulting from disappearance of micrometastases after neoadjuvant therapy. This was thought to be a significant advantage in terms of decreasing morbidity of treatment, particularly the late effects of radiotherapy.

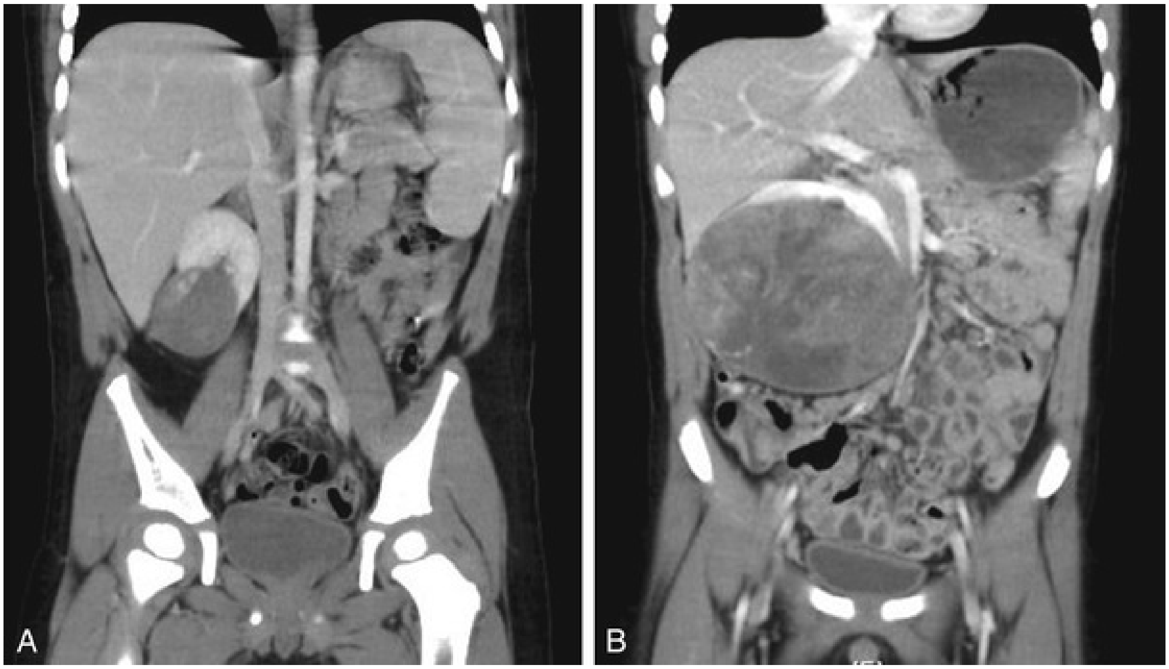

FIG. 53.10 (A) CT of a Wilms tumor that was pretreated with chemotherapy. (B) After 6 weeks of chemotherapy, the tumor is much smaller in size.

Early SIOP studies evaluated pre-nephrectomy XRT (Lemerle et al., 1976)**. SIOP-5 (1976–1980) showed that 4 weeks of AMD and VCR were as effective as pre-nephrectomy XRT in avoiding surgical tumor rupture and increasing the proportion of patients with low stage disease** (Lemerle et al., 1983)**. SIOP-6 (1980–1987) demonstrated that patients with "post-chemotherapy stage I" disease can safely be treated with 18 weeks of AMD and VCR** (Tournade et al., 1993)**. However, patients with "post-chemotherapy stage II" tumors and negative lymph nodes were found to have a higher rate of abdominal relapse if postoperative irradiation was omitted** (Tournade et al., 1993). An anthracycline was subsequently added for treatment of these children. SIOP-6 confirmed the need for a three-drug chemotherapy regimen after nephrectomy for patients with "post-chemotherapy stage II" lymph node positive and stage III tumors. SIOP-9 (1987–1993) demonstrated that the relapse rate for stage II patients with negative lymph nodes without radiation therapy was reduced with epirubicin (Tournade et al., 2001). This study also demonstrated that treatment with VCR and AMD for 4 weeks versus 8 weeks had comparable rates of stage distribution and tumor shrinkage in patients with stage I and III disease. The majority of tumor shrinkage was noted in the first 4 weeks of therapy. Radiotherapy was limited to patients with stage II node-positive and III disease resulting in 18% of patients being irradiated (Graf et al., 2000). There were 59 children with stage I to IV tumors who had complete tumor necrosis induced by chemotherapy, and 98% of these children had no evidence of disease at 5 years (Boccon-Gibod et al., 2000).

The SIOP 93-01 study (1993–2001), evaluated a reduction in postoperative therapy for patients with stage I intermediate risk and anaplastic Wilms tumor (deKraker et al., 2004; Reinhard et al., 2004b). Patients were randomized to receive either 4 or 18 weeks of postoperative chemotherapy with AMD and VCR. Two-year EFS was 91.4% after 4 weeks and 88.8% after 18 weeks of therapy, demonstrating that survival can be maintained while shortening the duration of post-nephrectomy therapy. Patients with stage II or III with low- or intermediate-risk histology received 4 weeks of dactinomycin and VCR before surgery (Graf et al., 2012). Postoperative chemotherapy consisted of dactinomycin, VCR, and epirubicin/doxorubicin for 27 weeks. Flank or whole-abdomen irradiation was given for stage III. With a median follow-up of 8 years, 5-year EFS was 90% and OS 95%. Patients with blastemal type histology had a worse prognosis with 62% EFS at 5 years. They made up only 10% of patients but contributed to one-third of the relapses and deaths. The other important prognostic factors were a large tumor volume at surgery and stage III disease.

The SIOP 2001 study asked the question whether patients with stage II and III intermediate-risk histology Wilms tumors could be safely treated without an anthracycline. Data from SIOP 93-01 had suggested that survival was not adversely affected when nonviable tumor was identified in the renal sinus and/or perirenal fat after preoperative chemotherapy (Vujanic et al., 2009). Between 2001 and 2009, 583 patients were randomized (Pritchard-Jones et al., 2015). For stage II or stage III intermediate-risk histology Wilms tumor, 2-year EFS was 92.6% for patients treated with DOX and 88.2% for treatment excluding DOX. OS was 96.5% and 95.8%, respectively. The SIOP group uses the response of the tumor to preoperative chemotherapy in their risk stratification (Vujanic et al., 2002). This includes not only percentage of necrosis but also on the predominant cell type in the residual viable tumor component. Patients with high-risk blastemal tumors continue to receive treatment with DOX, including stage I tumors (van den Heuvel-Eibrink et al., 2015). The intensified treatment for the latter patients yielded improved OS in SIOP 2001 with EFS of 96% (OS 100%)

compared with EFS of 71% (OS 90%) in SIOP 93-01.

United Kingdom Children's Cancer Study Group.

The UKCCSG has conducted several trials using prenephrectomy chemotherapy but, unlike SIOP, they perform biopsy before treatment (Mitchell et al., 2000; Pritchard et al., 1995; Pritchard-Jones et al., 2003). This is done to avoid giving chemotherapy to infants and children with benign tumors, which accounts for 1% of lesions thought to be Wilms tumor on imaging studies (Tournade et al., 2001). The other reason to perform biopsy is to avoid giving inappropriate chemotherapy to non–Wilms tumors, which often require more intensive therapy. The UKW3 trial noted a 12% incidence of non–Wilms tumors in patients with the typical features of Wilms tumor on imaging study (Vujanic et al., 2003). The UKW1 and UKW2 studies evaluated the single-agent VCR for treatment of stage I FH tumors (Mitchell et al., 2000; Pritchard et al., 1995). The OS of 96% compares well with two-drug chemotherapy, but age greater than 4 years was considered an adverse prognostic factor (Pritchard-Jones et al., 2003).

The UKW3 trial randomly assigned patients to either immediate surgery or to 6 weeks preoperative chemotherapy and then delayed surgery (Mitchell et al., 2006). EFS and OS at 5 years were similar in the two groups. Around 20% of survivors avoided treatment with doxorubicin or radiotherapy because of favorable stage distribution after preoperative therapy. They concluded, like the SIOP group, that all children with non-metastatic Wilms tumor should receive chemotherapy before tumor resection.

Adult Wilms Tumor

Wilms tumor occasionally occurs in adults. Earlier reports suggested that the outcome for adults with Wilms tumor was poor and that they require more intensive therapy (Arrigo et al., 1990). More recent reviews of adult patients with FH Wilms tumor have found improved survival compared with prior reports (Ali et al., 2012; Kalapurakal et al., 2004a; Reinhard et al., 2004a). The recommendation is that adult patients receive stage-appropriate combined modality therapy.

Relapse

A uniform approach for the treatment of tumor relapse was used in NWTS-5. Patients with relapsed Wilms tumor may be divided into risk groups according to

OS rates after salvage therapy (Spreafico et al., 2009). Children with non-anaplastic Wilms tumor who relapse after therapy with only VCR and/or AMD are considered standard risk and have survival rates in the 70% to 80% range (Green et al., 2007). Patients with non-anaplastic Wilms tumor who relapse after therapy with three or more agents are called high risk and have survival rates in the 40% to 50% range (Malagolowkin et al., 2008). The very high-risk group includes recurrent anaplastic or blastemal-type Wilms tumor and have survival rates in the 10% range (Reinhard et al., 2008). Further studies are needed to determine the optimal treatment strategies for the “high risk” and “very high-risk” groups and to define the role of high-dose myeloablative chemotherapy and stem cell rescue (Ha et al., 2013).

Preoperative Chemotherapy (COG Recommendations)

On the COG renal tumor protocols, treatment is dependent on surgical and pathological staging after immediate nephrectomy. There are, however, some situations in which preoperative chemotherapy is recommended. These include children for whom renal-sparing surgery is planned (Blute et al., 1987), tumors inoperable at surgical exploration (Ritchey et al., 1994), and tumor extension into the IVC above the hepatic veins (Ritchey et al., 1993b; Shamberger et al., 2001; Szavay et al., 2004). The last two conditions are associated with an increased risk for surgical complications if primary nephrectomy is performed (Ritchey et al., 1992).

Inoperable Tumors.

The surgeon, not the oncologist or radiotherapist, must make the determination that a tumor is inoperable. This decision should not be based on preoperative imaging studies, which can overestimate local tumor extension. As noted earlier, not all renal masses in children represent Wilms tumor (Vujanic et al., 2003). If the tumor is found to be unresectable, pretreatment with chemotherapy almost always reduces the bulk of the tumor and renders it resectable (Grundy et al., 2004; Ritchey et al., 1994). Patients who are staged with imaging studies alone and receive preoperative chemotherapy before nephrectomy are also at risk for understaging (Tournade et al., 1993). **Patients enrolled in COG studies determined to have an inoperable tumor are treated as stage III disease** (Dome et al., 2015). The number of patients in North America treated with preoperative chemotherapy has increased over time. On NWTS-3, only 5.4% of patients were treated as inoperable (Ritchey et al., 1994). For the recently completed COG AREN0532 and AREN0533 studies, approximately 20% of patients with overall stage III disease and 40% of patients with overall stage IV disease underwent delayed nephrectomy (Dome et al., 2015).

Repeat imaging is performed after 6 weeks of chemotherapy. Experience in SIOP has shown that the majority of reduction (48%) in tumor volume occurs in the first 4 weeks of therapy (Tournade et al., 2001) but that reduction extends out through 8 weeks (62%). After there has been adequate shrinkage of the tumor, definitive resection can usually be completed. A clinically good response (by imaging) is usually associated with a pathologically good response in terms of regressive histologic changes (Weirich et al., 2001; Zuppan et al., 1991). The converse is not always true. The distribution of histologic subtypes is different after preoperative chemotherapy compared with primary surgery, with differentiation of the tumor occurring after chemotherapy. Stromal- and epithelial-predominant tumors are found more often after treatment with preoperative chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised. Patients with progressive disease have a poor prognosis, and these patients require treatment with a more intensive chemotherapeutic regimen (Ora et al., 2007; Ritchey et al., 1994).

Bilateral Wilms Tumors.

Synchronous bilateral Wilms tumors occur in 5% to 7% of children with Wilms tumor (Blute et al., 1987; Coppes et al., 1989; Montgomery et al., 1991)**. Children with bilateral tumors should not undergo initial radical nephrectomy.** These children should receive preoperative chemotherapy with the goal of tumor shrinkage and renal-sparing surgery (Blute et al., 1987; Coppes et al., 1989; Hamilton et al., 2011; Kumar et al., 1998). Preservation of renal tissue is important to decrease the incidence of renal failure, which approaches 15%, at 15 years after treatment in patients with bilateral Wilms tumor (Breslow et al., 2005; Ritchey et al., 1996). The most common cause for renal failure was the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy. Complete nephrectomy can be avoided in the majority of patients if a careful protocol is followed and the surgery is performed by surgeons experienced in renal-sparing techniques (Davidoff et al., 2008; Fuchs et al., 2011).

The recently completed COG protocol (AREN0534) recommended that patients with bilateral Wilms tumor receive 6 weeks of chemotherapy before surgery. Biopsy was not required if the radiographic picture was consistent with Wilms tumor. Tumor response was assessed after 6 weeks with CT or MRI to determine the reduction in tumor volume and feasibility of partial resection. Patients with tumors amenable to renal-sparing procedures were allowed to proceed with surgery. **Tumors not responding to therapy required bilateral open biopsy to determine histology. Open biopsies are recommended because they are more accurate than percutaneous needle biopsies when assessing for anaplasia, and bilateral biopsies are recommend because anaplasia is found to be discordant between the two kidneys in 83% of children** (Hamilton et al., 2006). Biopsy is necessary because imaging cannot predict the histology of the tumor based on changes in volume of the tumor after chemotherapy (Olsen et al., 2004; Weirich et al., 2001). Failure to achieve a reduction in volume is likely a result of tumor differentiation (Fig. 53.11) (Anderson et al., 2002; Shamberger et al., 2006; Weirich et al., 2001). Differentiated tumors may show a poor clinical response to therapy, but they have an excellent prognosis if the tumor is completely excised. If renal-sparing surgery is not feasible, additional chemotherapy is then given based on the biopsy findings, but all patients were recommended to undergo surgical resection within 12 weeks of starting therapy. Continuing treatment beyond 12 weeks will not likely provide any additional reduction in tumor burden.

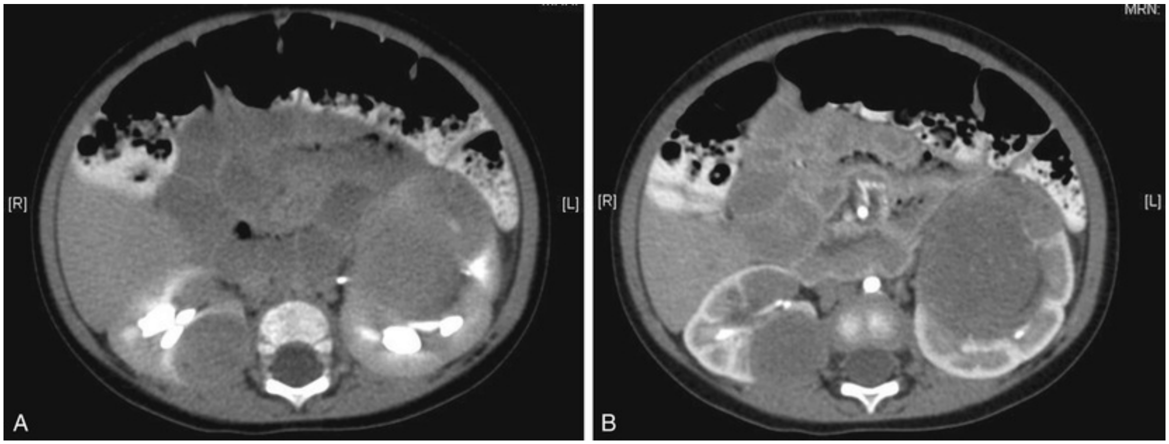

FIG. 53.11 Patient with bilateral tumors who was treated with chemotherapy. (A) CT before treatment. (B) CT after 12 weeks of chemotherapy, revealing only minimal decrease in the size of the tumors. Bilateral partial nephrectomies were performed, revealing mature tumor elements with rhabdomyoblastic differentiation.

At the time of second-look surgery, partial nephrectomy or wedge excision of the tumor is preferred with an attempt to achieve negative margins. Radical nephrectomy may be needed in a kidney with extensive tumor involvement. The kidney with the lower tumor burden is addressed first. Tumor enucleation may be considered in lieu of a formal partial nephrectomy. This is often needed for large centrally located tumors when removal of a margin of renal tissue would compromise the vascular supply to the kidney (Cozzi et al., 1996; Horwitz et al., 1996). The concern is that enucleation will be more likely to result in positive surgical margins. For FH tumors, adjuvant therapy may still achieve a good outcome (Cozzi et al., 1996; Davidoff et al., 2008; Horwitz et al., 1996). However, if there is anaplasia in the resected specimen, a positive margin will adversely affect survival and requires additional resection. Even when large bilateral masses remain after initial chemotherapy, a high percentage of children can be successfully managed with renal-sparing surgery (Davidoff et al., 2008). It is easy to underestimate the amount of renal parenchyma that can be salvaged as a result of compression by the tumor; therefore nephron-sparing surgery should be considered in all patients (Fig. 53.12). One concern regarding enucleation of large centrally located tumors is the potential for positive surgical margins. Kieran et al. (2013b) reported a 23% incidence of positive surgical margins in a cohort of 21 patients with bilateral Wilms tumor undergoing renal-sparing surgery. They did not demonstrate an increased risk of local recurrence, but this was a small number of patients, with all receiving 10.5-Gy flank radiation.

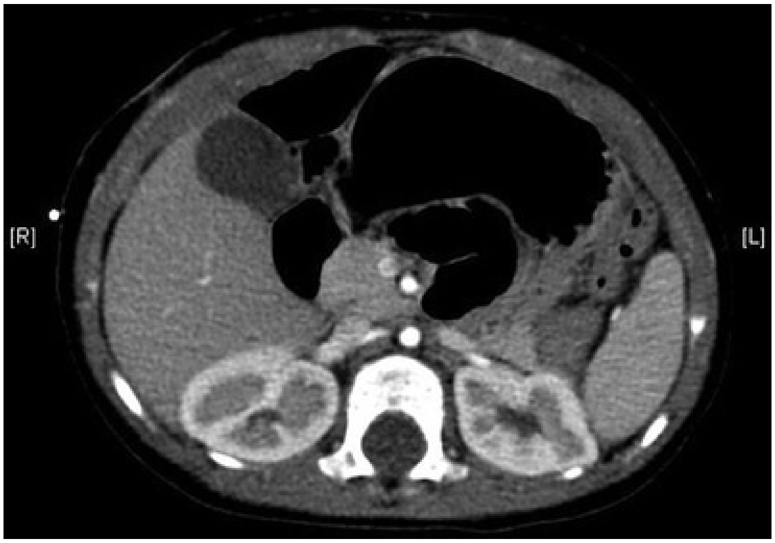

FIG. 53.12 Postoperative image from patient shown in Fig. 53.11.

Demonstrates that the kidneys have pretty near normal volume after resection of the bilateral tumors.

The COG AREN0534 study enrolled 195 patients with bilateral Wilms tumor (Ehrlich et al., 2017). Of the 189 evaluable patients, 84.0% underwent definitive surgical treatment (partial or complete nephrectomy or wedge resection in at least one kidney) by 12 weeks after initiation of chemotherapy. Thirty percent of those patients who achieved definitive surgical resection within the 12-week specified aim did so by the 6-week evaluation point. Surgical approaches included unilateral total nephrectomy with contralateral partial nephrectomy (48%), bilateral partial nephrectomy (35%), unilateral total nephrectomy (10.5%), unilateral partial nephrectomy (4%), and bilateral total nephrectomies (2.5%). The 4-year EFS and OS were 82.1% and 94.9%, respectively. This is compared with 4-year EFS and OS of 56% and 80.8% on NWTS-5.

Bilateral nephrectomies and dialysis are rarely required when the tumors fail to respond to chemotherapy and radiation therapy. This is the most common cause of renal failure in patients with bilateral Wilms tumor (Ritchey et al., 1996). Fortunately, anephric patients can still be administered chemotherapy with some modifications (Feusner et al., 2008). The recommended interval between successful completion of treatment of the Wilms tumor and renal transplantation varies (Kist-van Holthe et al., 2005; Penn, 1979). Some advocate a waiting period of 2 years to ensure that the patient does not develop metastatic disease; others have found that a 1-year interval is sufficient (Gregoriev et al., 2012). Patients who develop renal failure after renal-sparing surgery should have removal of the remaining renal tissue before transplant to prevent tumor recurrence after starting immunosuppression (Kubiak et al., 2004).

All patients treated for bilateral Wilms tumor require close long-term follow-up. SIOP investigators noted that late relapses have occurred in patients with bilateral Wilms tumor more than 4 years after treatment and recommended long-term follow-up (Coppes et al., 1989). These patients should also have frequent assessment of renal function, urine protein, and blood pressure.

Partial Nephrectomy for Unilateral Tumors.

There have been a number of papers examining the role of parenchymal-sparing procedures in children with unilateral Wilms tumors (Cost et al., 2012; Haecker et al., 2003; McLorie et al., 1991; Wilde et al., 2014; Zani et al., 2005). The primary motivation for this approach is concern about late occurrence of renal dysfunction after unilateral nephrectomy. However, **the incidence of renal**

failure after nephrectomy for most children with unilateral Wilms tumor is low, 0.6% at 20 years after treatment (Breslow et al., 2005; Lange et al., 2011). **The risk of renal failure is higher for patients with genitourinary anomalies, DDS, and WAGR.** As noted earlier, this is a result of mutation of *WT1,* which is necessary for normal renal development. Syndromic patients are more likely to have smaller tumors identified on screening studies that are more amenable to renal-sparing surgery (Romao et al., 2012; Scalabre et al., 2016).

Most Wilms tumors are too large at diagnosis to allow partial nephrectomy. After preoperative chemotherapy, partial nephrectomy can be performed in 10% to 15% of patients. However, this higher percentage is only achieved if the clinician is more aggressive in proceeding with nephron sparing surgery (NSS). The SIOP 2001 study restricted NSS for polar or peripherally non-infiltrating tumors (Wilde et al., 2014). They reported that 3% of tumors met the criteria for NSS. Only the occasional case of Wilms tumor will involve a lesion small enough to allow partial nephrectomy at diagnosis—for example, tumors detected on screening studies for Beckwith-Wiedemann syndrome and aniridia (see Fig. 53.6). Even in the young children with very-low–risk stage I tumors, it is estimated that less than 10% of children would be amenable to partial nephrectomy (Ferrer et al., 2013). As noted earlier, there are concerns regarding staging after chemotherapy, requiring some patients to receive added therapy to prevent local recurrence. Another concern is the increased risk for local recurrence after partial nephrectomy (Haecker et al., 2003; Horwitz et al., 1996; Wilde et al., 2014). Patients who develop intra-abdominal relapse have a markedly decreased survival (Shamberger et al., 1999).

The COG AREN0534 study also included a renal-sparing protocol for select patients with unilateral Wilms tumors known to be at risk for bilateral disease or at increased risk for renal failure. These patients were managed with a strict surgical protocol to minimize risk for residual disease (Cozzi et al., 2004). The protocol required that the lesion be completely excised with a margin of normal renal parenchyma. These patients should not undergo partial nephrectomy if the tumor cannot be removed at stage I. Patients with high-risk histologic patterns such as anaplasia or persistent blastemal-predominant tumor after chemotherapy should be treated with complete nephrectomy because these tumors have resistance to chemotherapy (Reinhard et al., 2004b). Results of AREN0534 for patients with unilateral tumors have not been published.

Late Effects of Treatment

The 5-year survival rate for childhood cancers has increased over the past decades to more than 80%. Achieving these high cure rates requires exposure of normal healthy tissue to potential harm with many organ systems subject to the late sequelae of anticancer therapy. These survivors are at increased risk for numerous chronic health conditions, hospitalizations, and reduced productivity because of health problems (Phillips et al., 2015). Clinicians must be aware of the spectrum of problems that face children as they grow into adulthood. Our understanding of late effects in Wilms tumor survivors has been advanced through several large studies. The NWTSG Late Effects Study followed patients treated in NWTS-1 to NWTS-5. The original Childhood Cancer Survivor Study (CCSS) was a retrospectively ascertained cohort of childhood cancer survivors diagnosed from 1970 to 1986. More than 14,000 survivors were surveyed and followed for long-term health outcomes. Because of the significant changes in therapy for children with cancer over the past 30 years, a second group of about 10,000 survivors diagnosed between 1987 and 1999 were also recruited for the study. Similar efforts are also conducted in other countries, some of which are population-based cohort studies (Wong et al., 2016).

The CCSS reported a cumulative incidence of 65% for all chronic health conditions in Wilms tumor survivors at 25 years after completion of therapy (Termuhlen et al., 2011). These rates continue to increase with longer periods of follow-up (Phillips et al., 2015). The cumulative incidence of severe (grades 3 or 4) chronic health conditions was 24% (Termuhlen et al., 2011).

Mortality

The NWTSG Late Effects Study showed that survivors remain at elevated risk for death compared with the general population for many years after their original diagnosis (Cotton et al., 2009). A more recent report from the CCSS has shown that mortality for survivors of childhood cancer has decreased for those patients treated in the 1990s compared with the early 1970s (Armstrong et al., 2016). This is attributed to changes in therapy (e.g., reduction the number of patients exposed to radiotherapy or anthracyclines).

Fertility and Pregnancy

Gonadal radiation can produce hypogonadism and temporary azoospermia in boys (Kinsella et al., 1989). The severity of damage is radiation dose dependent.

The Leydig cells are more radioresistant than the germ cells, but higher doses can produce damage, resulting in inadequate production of testosterone. This can result in delayed sexual maturation. Chemotherapeutic agents can also adversely affect testicular function (Mustieles et al., 1995). Pelvic irradiation and exposure to alkylating agents are risk factors for ovarian failure and premature menopause in female Wilms tumor survivors (Green et al., 2009). Very few pregnancies have been reported in patients who received whole abdominal radiation therapy (Green et al., 2010). Pregnancy complications were evaluated extensively through the NWTSG. The offspring of irradiated female patients are at risk for low birth weights and premature birth. Radiation portals that include the pelvis and doses exceeding 20 Gy increase the risk of miscarriage (Kalapurakal et al., 2004b). Wilms tumor survivors treated with abdominal radiotherapy are also at increased risk of hypertension complicating pregnancy (Reulen et al., 2017).

Second Malignancies

An increased incidence of second malignant neoplasms has been noted in children treated for Wilms tumor. There is a 1% cumulative incidence at 10 years postdiagnosis, and a rising incidence thereafter (Breslow et al., 1988b, 2010; Taylor et al., 2008). One of the greatest risk factors is prior irradiation, and most tumors occur in the radiation field (Bassal et al., 2006; Breslow et al., 1988b; Taylor et al., 2008). The incidence of leukemia is highest during the first 5 years after Wilms tumor treatment. The incidence of solid tumors increases with longer periods of follow-up (Lee et al., 2015).

Cardiac Effects

The risk of cardiotoxicity in Wilms tumor survivors has been carefully studied. In a review of patients entered in NWTS-1, NWTS-2, NWTS-3, and NWTS-4, the frequency of congestive heart failure was 4.4% among DOX-treated patients who received this drug as part of their initial chemotherapy regimen (Green et al., 2001b). The risk was increased if the patient received whole-lung or left-flank irradiation. Only one patient with congestive heart failure received a DOX cumulative dose below 150 mg/m^2, which is used in contemporary North American treatment regimens. However, subclinical cardiotoxicity was not assessed, and it is possible that clinical effects with modern regimens will become apparent with longer follow-up. The British CCSS has found that cardiac problems were the second most common cause of mortality more than 30 years after Wilms tumor diagnosis (Wong et al., 2016).

Other Renal Tumors

Clear Cell Sarcoma of the Kidney

CCSK accounts for 3% of renal tumors reported to the NWTSG. The tumor derives its name from the clear cytoplasm of the predominant cell type (Schmidt and Beckwith, 1995). **Important predictors of improved survival are lower stage, younger age at diagnosis, treatment with DOX, and absence of tumor necrosis** (Argani et al., 2000). **The addition of doxorubicin improved OS and relapse-free survival** (Argani et al., 2000; D'Angio et al., 1989; Seibel et al., 2004). Patients with stage I tumors (using the current criteria of absence of renal sinus invasion) had a 98% survival rate. Unlike anaplastic Wilms tumor, even stage I CCSK lesions are associated with increased rates of relapse and require postoperative irradiation. Long-term follow-up of CCSK patients is needed because 30% of relapses occurred more than 3 years after diagnosis and some as late as 10 years. Unlike Wilms tumor, **CCSK is associated with bone and brain metastases.** Bilateral involvement has thus far not been reported, nor has the presence of Wilms tumor associated congenital anomalies such as aniridia or hemihypertrophy. Patients with CCSK were treated on NWTS-5 with a regimen combining VCR, DOX, cyclophosphamide, and etoposide in an attempt to further improve the survival of this high-risk group. However, outcomes for patients with CCSK treated on NWTS-5 were similar to that seen on NWTS-4 (5-year RFS and OS of 79% and 89%, respectively) (Seibel et al., 2018). Stage was found to be highly predictive of outcome; 5-year RFS rates for stages I, II, III, and IV on NWTS-5 were 100%, 88%, 73%, and 29%, respectively. Similar outcomes have been reported by SIOP investigators (Furtwangler et al., 2013).

Rhabdoid Tumor of the Kidney

RTK is the most aggressive and lethal childhood renal tumor that accounts for 2% of renal tumors. RTK and CCSK occur in renal and extrarenal locations, suggesting an origin from a non–organ-specific mesenchymal cell. These tumors are characterized by loss of function of the *SMARCB1/INI1/SNF5/BAF47* gene in chromosome band 22q11.2 (Biegel et al., 1999). Consistent with its role as a tumor suppressor gene, tumors arise after inactivation of both alleles of *SMARCB1*. Germ-line alterations of the *SMARCB1* gene are found in one-third of the patients (Eaton et al., 2011). Germ-line mutations of *INI1* have been identified in renal rhabdoid tumors. Staining for the products of the *INI1* gene can be useful because rhabdoid tumor of the kidney is consistently negative (Hoot et al., 2004).

Typical clinical features include early age of diagnosis (median age <16 months), advanced stage, resistance to chemotherapy, and high mortality (Amar et al., 2001; Tomlinson et al., 2005). Younger age at diagnosis is an adverse prognostic factor. **RTK is distinguished by its propensity to metastasize to the brain** (D'Angio et al., 1993). There is no standard therapy for RTK. Intensification of therapy with high-dose chemotherapy and autologous stem-cell transplantation have not yielded improved survival (Furtwangler et al., 2018).

Congenital Mesoblastic Nephroma

CMN is the most common renal tumor in infants with a mean age at diagnosis of 3½ months (Howell et al., 1982; van den Heuvel-Eibrink et al., 2008). **This is the most common renal tumor diagnosed on antenatal ultrasound (LeClair et al., 2005).** Congenital mesoblastic nephroma is a very firm tumor on gross examination, and the cut surface has the yellowish-gray trabeculated appearance of a leiomyoma. There are three histologic subtypes: classic, cellular, and mixed (showing areas of classical and cellular). The classic subtype, characterized by interlacing sheets of bland spindle cells, resembles infantile fibromatosis. The cellular variant, with a solid sheet-like growth pattern and frequent mitoses, is virtually identical histologically to congenital fibrosarcoma (Beckwith, 1986; Gormley et al., 1989; Joshi et al., 1986). Both tumors have a similar translocation that fuses the *ETV6* (TEL) gene from 12p13 with the 15q25 neurotrophin-3 receptor gene, *NTRK3* (Argani et al., 1998; Vokuhl et al., 2017). A SIOP/GPOH showed that patients with cellular type CMN who have translocation-positive tumors had a significantly superior RFS (5-year RFS: 100% vs. 73%). In CMN, tumor induction is postulated to occur at a time when the multipotent blastema is predominately stromagenic (Snyder et al., 1981; Tomlinson et al., 1992). WT1 is not expressed in CMN (Tomlinson et al., 1992).

The most important aspect of CMN is the usually excellent outcome with radical surgery only (Howell et al., 1982). The tumor can extend into the hilar or perirenal soft tissue; therefore complete surgical resection is important (Beckwith, 1986). Local recurrence and metastasis can occur particularly with the cellular variant of CMN (Fitchey et al., 2003; Gormley et al., 1989; Joshi et al., 1986). The risk of recurrence is thought to be less in children under 3 months of age at diagnosis, but metastases have been reported in a few infants (Heidelberger et al., 1993). Neither chemotherapy nor radiation therapy is routinely recommended (Howell et al., 1982), but consideration for adjuvant treatment should be given to patients with cellular variants that are incompletely resected (Gormley et al., 1989). There are reports demonstrating response of inoperable and recurrent tumors to chemotherapy (Loeb et al., 2002; McCahon et al., 2003).

Solitary Multilocular Cyst and Cystic Partially Differentiated Nephroblastoma

Solitary multilocular cyst, or multilocular cystic nephroma, is an uncommon, benign renal tumor. Fifty percent of multilocular cysts are found in young children, usually boys. The second peak incidence occurs in young adult women (Eble and Bonsib, 1998; Luithle et al., 2007). Although the majority of cases of multilocular cystic renal disease have been unilateral, there are rare reports of bilateral cases (Ferrer and McKenna, 1994). The gross appearance of the tumor is its most distinguishing feature. The cut surfaces reveal a well-encapsulated multilocular tumor composed of various-size cysts compressing the surrounding renal parenchyma. This tumor is distinguished by the finding of only mature cell types within the septa of the cyst wall. Multilocular cystic nephroma is cured by nephrectomy, but recurrence has occurred after incomplete excision by partial nephrectomy. If partial nephrectomy is considered, frozen section is indicated to exclude cystic partially differentiated nephroblastoma (CPDN) or clear cell sarcoma, which can occasionally have a similar appearance.

Another entity reported in the literature with similar features is CPDN. The majority of these lesions occur in the first 2 years of life (Blakely et al., 2003; Joshi and Beckwith, 1989; Luithle et al., 2007). Eble and Bonsib (1998) recommend that multilocular cystic nephroma and CPDN be considered the same entity. They are indistinguishable radiographically. Histologic examination reveals that blastemal cells or nephrogenic rests may be found in the septa of both tumors. Surgery is curative in almost all patients with recurrence being the result of incomplete resection (Blakely et al., 2003; Eble and Bonsib, 1998). In a review of 21 children with cystic partially differentiated nephroblastoma (CPDN) reported to the NWTSG, there was 100% survival. Eight were treated with surgery alone (Blakely et al., 2003). Thirteen patients received postoperative chemotherapy, including two patients with stage II disease.

Metanephric Adenofibroma

Another tumor with prominent stromal features that can resemble CMN is metanephric adenofibroma (Arroyo et al., 2000). The epithelial component of these tumors can range from inactive metanephric adenoma to Wilms tumor. Other lesions contain areas morphologically identical to papillary renal cell carcinoma. This uncommon entity may be derived from ILNR (Arroyo et al., 2000). Metanephric adenofibromas with a composite Wilms tumor component occur at a young age (mean of 12 months) similar to other ILNR-related Wilms tumors that develop in patients with DDS and aniridia. None of these tumors have recurred after nephrectomy, but all have been treated with Wilms tumor chemotherapy.

Renal Cell Carcinoma

Renal cell carcinoma (RCC) is the most common renal malignancy in the second decade of life. Only 5% of RCCs occur in children (Broecker, 1991; Geller et al., 2015; Hartman et al., 1982). An abdominal mass is the most common presentation, but hematuria is more common than in Wilms tumor (Broecker, 1991). Imaging studies cannot differentiate RCC from other solid renal tumors. **There is a higher incidence of papillary RCC in children** (Renshaw et al., 1999; Selle et al., 2006). However, the most common histology of RCC in children and adolescents, at approximately 50%, is translocation-associated RCC (Geller et al., 2015). **These tumors, typically seen in adolescence or young adults, are genetically unique in that they have chromosome translocations involving a common breakpoint in the *TFE3* gene located at Xp11.2** (Bruder et al., 2004). These tumors differ from adult RCC in that immunoreactivity for epithelial markers is reduced or absent. There is also an increased risk of lymph node involvement (40%–50%), and presentation is at a higher stage than adult RCC (Geller et al., 2015).

Another type of RCC more often seen in children is renal medullary carcinoma found in patients with sickle cell hemoglobinopathy (Swartz et al., 2002). The median age at presentation is 13 years, but it can be found in much younger children. It is a highly lethal tumor. A recent report from COG noted that 22 of 25 patients (88%) with renal medullary carcinoma in their Biology and Banking Study (AREN03B2) were diagnosed with stage IV disease at diagnosis (Sandberg et al., 2017).

Complete tumor resection is the most important determinant of outcome in RCC. Raney et al. (1983) found that all children with stage I lesions survived, and others have reported 64% to 80% survival for stage I and II tumors (Aronson et al., 1996; Castellanos et al., 1974; Dehner et al., 1970). Partial nephrectomy has been used in pediatric patients with RCC, but outcome data are limited (Cook et al., 2006). Younger age at diagnosis is a favorable prognostic factor (Raney et al., 1983). Regional lymph node involvement does not portend the same poor prognosis as adult renal cell carcinoma (Geller and Dome, 2004). Geller et al. (2008) reported that patients with TFE+ translocation and positive nodes were found to have 93% survival at a median follow-up of 4.3 years. However, others have noted higher rates of relapse (Perlman, 2010). Like RCC in adults, these tumors are generally not responsive to chemotherapy or radiation therapy, although case reports of successful adjuvant treatment have been published (Chowdhury et al., 2013).

Angiomyolipoma

Renal angiomyolipoma is a hamartomatous lesion that is only rarely seen in childhood. The majority of adult patients have sporadic angiomyolipomas. In children, they are most commonly detected in patients with the tuberous sclerosis complex (TSC), and presentation is more often bilateral in these patients (Bissler et al., 2016; Ewalt et al., 1998; Warncke et al., 2017). Angiomyolipoma develops in 50% to 80% of patients with TSC. The lesions progressively enlarge through childhood with an apparent growth spurt in teenagers and young adults. Warncke et al. (2017) noted increase annual growth in those TSC patients older than 11 years and those with AMLs smaller than 2 cm in size. Annual ultrasounds are recommended with consideration of MRI for those older than 11 years and having lesions smaller than 2 cm. Other renal lesions found in the TSC include simple cysts, polycystic kidney disease, and RCC. Renal cysts occur in up to 30% of patients with TSC. Mutations of one of two genes on chromosome 9 *(TSC1)* and chromosome 16 *(TSC2)* are found in 85% of TSC patients (Crino et al., 2006). It has been postulated that these genes act as tumor suppressor genes and that the LOH of *TSC1* or *TSC2* may explain the progressive growth pattern of renal lesions seen in these patients (Henske, 2004).

Patients with angiomyolipomas resulting from tuberous sclerosis are at risk for hemorrhage and impaired renal function (Bissler et al., 2016). For many years, the threshold diameter for intervention has been more than 4 cm. Recent data in adult patients with sporadic angiomyolipoma suggest that intervention can be delayed until the diameter exceeds 6 cm (Kuusk et al., 2015). The International TSC Consensus Group recommends intervention for lesions larger than 3 cm in diameter (Kingswood et al., 2016). Lesions in TSC patients that are larger than 3 cm and enlarging appear to be at greatest risk for bleeding. **The first-line treatment for children with growing lesions** (Fig. 53.13) **is with mTOR inhibitor, and embolization or surgery are second-line treatments.**

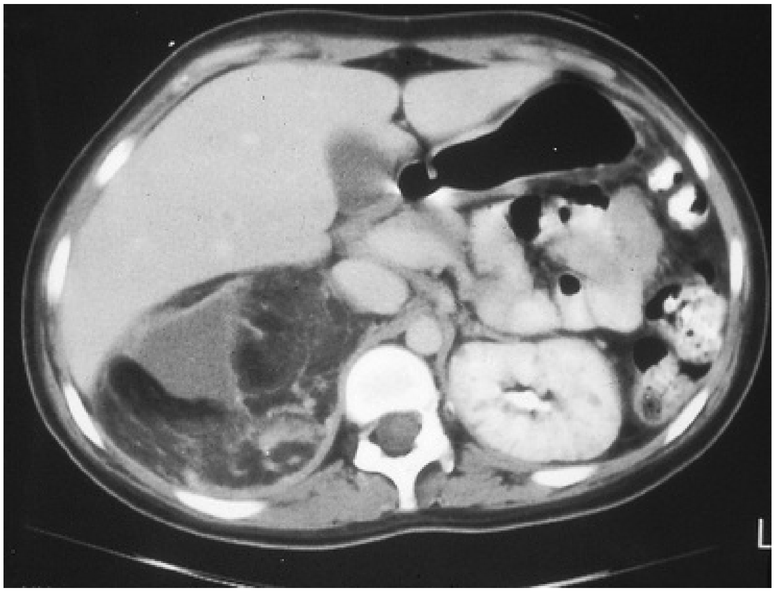

FIG. 53.13 Angiomyolipoma of the right kidney in a patient with tuberous sclerosis.

The main problems with embolization are risks of damage to infarction of normal adjacent renal parenchyma and risk of short-term complications and that it will not prevent other smaller lesions from progressing. Repeat intervention is required in 35% of patients undergoing embolization (Kuusk et al., 2015). Embolization is reserved for patients with active bleeding.

TSC1 or *TSC2* mutations in patients with TSC give rise to hyperactivation of the mTOR pathway. The first mTOR inhibitor studied for TSC patients was sirolimus. The renal studies all showed that sirolimus was very effective at preventing enlargement of the lesions and also significantly reducing their size, while the medication was taken continuously. When discontinued after 12 months, the angiomyolipomata started to enlarge again, demonstrating that the mTOR inhibitors must be continued (Bissler and Kingwood, 2016).

A randomized placebo-controlled trial (EXIST-1) reported that 42% of patients had at least a 50% reduction in total volume of angiomyolipoma after treatment with everolimus compared with 0 of placebo (Bissler et al., 2013). The patients were all age 18 years or older. An extended follow-up study (EXIST-2) has shown that 14% of patients will experience some progression of the angiomyolipomas (Bissler et al., 2017). No renal bleeding or nephrectomies were reported.

Some lesions are fat poor, and differentiation from other renal tumors—for example, RCC—on imaging studies can be difficult (Hindman et al., 2012). In some cases, biopsy of the lesion may be needed to confirm diagnosis of angiomyolipoma before proceeding with treatment. Nephron-sparing approaches are recommended in children with TSC because of the presence of multiple, bilateral lesions and the risk of development of new lesions.

Key Points: Renal Tumors

- Deletions of *WT1*, located on chromosome 11p, are found in patients with aniridia and Wilms tumor. Mutations of *WT1* occur in DDS.
- Local recurrence is increased in Wilms tumor patients with local tumor spillage, and this is not classified stage III disease. The 2-year survival rate after local recurrence is 43%.
- Patients with bilateral Wilms tumor should be treated with preoperative chemotherapy. This will allow more patients to undergo renal-sparing surgery in an attempt to decrease the risk of renal failure.
- CMN is the most common renal tumor in infants.

Pediatric Urologic Oncology

Bladder and Testis

Fernando A. Ferrer MD, FACS, FAAP

Since the first Intergroup Rhabdomyosarcoma Study (IRS-I 1972–1978), treatment strategies for patients with bladder prostate rhabdomyosarcoma (B/P RMS) have changed dramatically. Primary anterior exoneration (Ferrer et al., 2006; Horn and Enterline, 1958) has been replaced by organ preservation strategies. In IRS-IV (1993–1997) the bladder preservation rate among 88 analyzed patients was approximately 62%, significantly improved from that of IRS-I (23%) (Arndt et al., 2004). More recent studies from the European groups have demonstrated even higher rates of bladder preservation. Detailed long-term evaluation of bladder function remains lacking; thus the true efficacy of this approach remains somewhat uncertain. The relative roles of surgery versus radiotherapy in local control remain a subject of debate. Progress in the molecular/genomic characterization of rhabdomyosarcoma (RMS) has changed risk stratification and provided new insights into molecular mechanistic drivers, proving to be the most significant advances in RMS.

Epidemiology and Syndromic Associations

Approximately 350 cases of RMS are diagnosed annually in the United States; of these 15% to 20% arise from the genitourinary system (Crist et al., 2001; Maurer et al., 1988)**. RMS is the most common soft tissue sarcoma in children and is the third most common pediatric solid tumor, representing 5% to 15% of all childhood solid tumors.** B/P RMS demonstrates a bimodal age distribution with incidence peaking from ages 0 to 2 years and then again in adolescence. Males are preferentially affected. Causality remains unclear. Reports have suggested a higher risk of RMS in children with poor prenatal care or those conceived with assisted reproductive techniques, but overall, as with other childhood cancers, genetic factors are considered more important in pathogenesis than environmental factors (Shrestha et al., 2013; Williams et al., 2013).

Most cases of RMS are considered to be sporadic; however, a genetic basis is inferred from the association of RMS with certain syndromic conditions. These include Li-Fraumeni syndrome, basal cell nevus syndrome, Costello syndrome, Noonan syndrome, and multiple endocrine neoplasm type 2A (MEN 2A).

Li-Fraumeni syndrome results from germline mutations of the p53 tumor suppressor gene. Patients are predisposed to sarcomas, breast cancer, brain tumors, adrenal carcinoma, and leukemia. The overall cancer risk in affected individuals may be as high as 50% by age 30. Soft-tissue sarcomas, typically seen by age 10, account for 15% to 20% of tumors in these patients (Diller et al., 1995; Malkin et al., 1990). Neurofibromatosis is an autosomal dominant disorder. Deregulation of Ras protein function predisposes patients to malignancy (Oguzkan et al., 2006). In IRS-IV the incidence of neurofibromatosis-1 (NF-1) among enrollees was noted to be 20 times greater than in the normal population. **The lifetime risk of RMS has been estimated at 10% among NF-1 patients** (Sung et al., 2004) **who have a particular predilection for B/P RMS, prompting some to recommend surveillance** (Sung et al., 2004). Basal cell nevus, or Gorlin syndrome, confers constitutive activation of the hedgehog-signaling pathway as a result of defects in the *PTCH* gene (Hahn et al., 1996; Johnson et al., 1996). These abnormalities cause tumor cell resistance to apoptosis (Kappler et al., 2003). This syndrome is characterized by overgrowth features, skeletal abnormalities, and benign and malignant tumors. Patients are at particular risk for basal cell carcinoma, medulloblastoma, and RMS. Noonan syndrome is distinguished by facial abnormalities, short stature, and cardiac abnormalities. Hematologic and solid tumors result from PTPN11 abnormalities affecting the Ras-MAPK signaling pathways (Jongmans et al., 2011). Costello syndrome is an autosomal dominant disorder, which manifests clinically as mental retardation, unusual facial features, heart abnormalities, and short stature (Quezada and Gripp, 2007). **In Costello syndrome, permanent activation of *HRAS* results in unchecked cell division** (Rauen, 2007)**. Cancer may eventually occur in 15% of affected individuals. In one report of 200 patients, 13 (6.5%) eventually developed pelvic RMS, prompting a recommendation for screening ultrasounds every 3 to 6 months** (Gripp et al., 2002). MEN 2A is associated with medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. It is inherited in an autosomal dominant fashion and results in activating mutations of the *RET* proto-oncogene. Alveolar RMS (ARMS) has been reported in these patients, and some have recommended screening (Jones et al., 2010).

Pathology and Molecular Biology

The RMS histologic classification system was originally developed by Horne and Enterline (1958) and included four subtypes: embryonal, alveolar, pleomorphic, and undifferentiated. **Recognition that pleomorphic tumors were in fact anaplastic variants of embryonal (ERMS) or ARMS led to consolidation of the original system into the three histologic categories used today: embryonal, alveolar, and undifferentiated** (Kodet et al., 1993)**. Histology is an independent prognostic indicator. Recently molecular staging has been formally introduced into Childrens Oncology Group (COG) protocols.**

ERMS is the most common form of RMS and the predominant bladder histology. Two variants of ERMS account for up to two-thirds of all genitourinary RMS: sarcoma botryoides and spindle cell. These tumors are most common in young children and have a survival rate of 85% to 90% (Ferrer and Ritchey, 2006). The “botryoid” variant is a polypoid tumor, often appearing as a “cluster of grapes.” Botryoides arise within a hollow viscus. Spindle cell variants are commonly found in the paratesticular region.

Histologically, ERMS resembles fetal striated muscle correlating to a gestational age of 7 to 10 weeks. Cells are spindle shaped with minimal cytoplasm, associated with larger cells harboring abundant eosinophilic cytoplasm or alternatively small, dark ovoid cells. Some cells may demonstrate characteristic cross striations (Fig. 54.1; Ferrer and Ritchey, 2006; Horn and Enterline, 1958). ARMS is the second most common histologic type of RMS. It occurs most frequently in adolescents and young adults in the extremities and trunk. Histologic appearance correlates with striated muscle of 10 to 21 weeks’ gestational age. Small, round tumor cells form irregular nests that give the appearance of alveolar spaces (see Fig. 54.1; Horn and Enterline, 1958). ARMS expresses myogenin, a fetal myogenic regulatory gene, which serves as a useful immunohistochemical marker for ARMS (Dias et al., 2000). Myogenin staining is absent or weak in ERMS. Compared with ERMS, ARMS metastasizes more frequently and has a worse prognosis (Crist et al., 2001; Stevens et al., 2005). Undifferentiated tumors are the least common form of RMS and carry a poor prognosis. Histologically, they appear as primitive round cells with scant cytoplasm and lack common antigenic markers (Dodd et al., 1989; Parham et al., 1991).

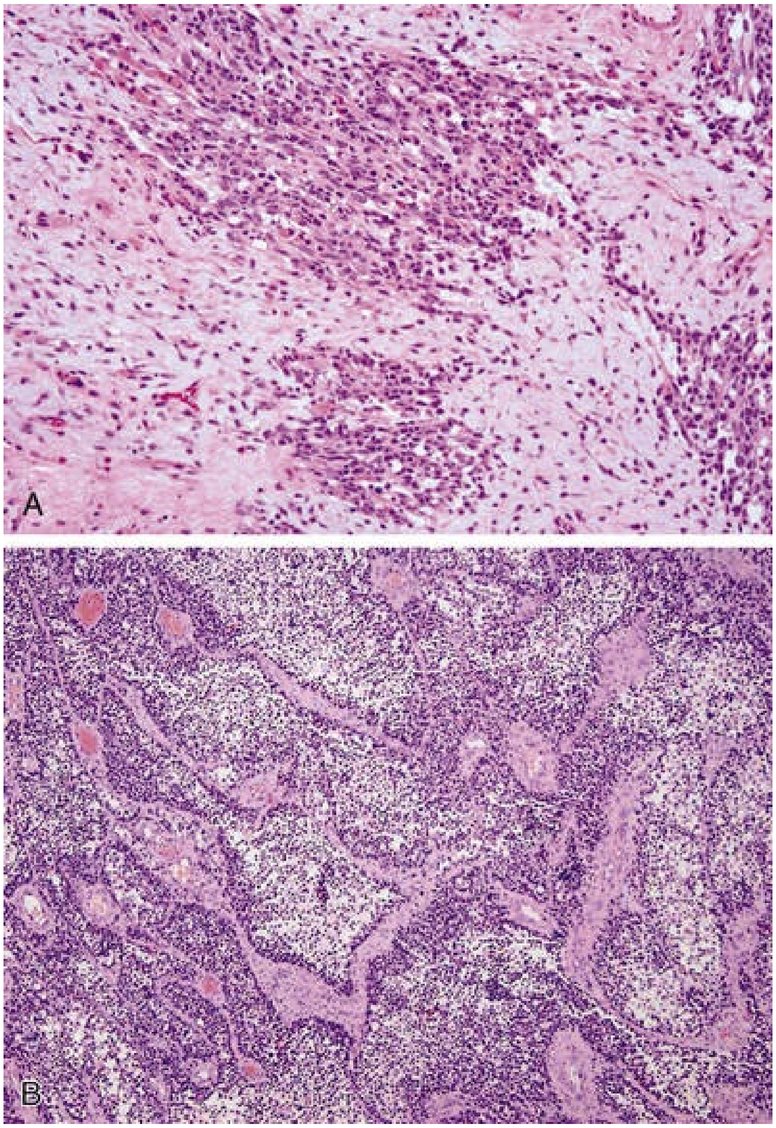

FIG. 54.1 Histologic images of common rhabdomyosarcoma variants. (A) Embryonal rhabdomyosarcoma (hematoxylin and eosin, ×200). (B) Alveolar rhabdomyosarcoma (hematoxylin and eosin, ×100). (Courtesy Cheryl Coffin, Vanderbilt University Medical Center.)

Histologic diagnosis is determined through standard immunohistochemistry and ultrastructural examination. Myogenic markers such as desmin, muscle-specific actin, myosin, and myoglobin are routinely used. As mentioned earlier, nuclear transcription factors that initiate myogenesis, MyoD and myogenin, are also being used (Cessna et al., 2001; Morotti et al., 2006; Parham and Barr, 2013).

The most significant recent development in RMS research is the discovery of oncogenic fusion proteins produced by chromosomal translocations. Histologic and clinical differences between ERMS and ARMS have long been recognized.

Only recently has molecular genetic analysis been able to distinguish two distinct subtypes of ARMS: fusion positive and fusion negative. Translocations between chromosomes 2;13 or 1;13 result in disruption of specific genes in 2q35 or 1p30 and 13q14. Rejoining these segments leads to the formation of fusion genes. The involved genes on chromosomes 2 and 1 are *Pax3* and *Pax7*. These genes are members of the paired-box family of transcription factors (Barr et al., 1993; Davis et al., 1994). The chromosome 13 fusion partner is *FOXO1*, which encodes transcription factors from the forkhead family (Davis et al., 1994; Galili et al., 1993). **The resulting fusion genes *Pax3-FOXO1* and *Pax7-FOXO1* are believed to encode proteins involved in ARMS pathogenesis and confer more aggressive phenotype** (Parham and Barr, 2013)**. It appears that roughly 80% of ARMS are fusion positive.**

The clinical relevance of these molecular features has been highlighted in a report from the COG sarcoma committee in a survival analysis; patients with intermediate-risk RMS, *Pax3-FOXO1*$^+$ ARMS (n = 85), *Pax7*-FOXO1$^+$ ARMS (n = 23), translocation-negative ARMS (n = 21), and 305 patients with ERMS were evaluated for event-free survival (EFS) and overall survival (OS). As expected, EFS and OS were worse at 5 years for those with ARMS compared with those with ERMS. ***Pax3/ Pax7-FOXO1*$^+$ fusion-positive patients had inferior EFS compared with those with fusion-negative ARMS and ERMS** (Fig. 54.2). In addition, OS proved worse for those with *Pax3* fusion compared with those with *Pax7* fusion (Skapek et al., 2013). These findings provide insight into the 20% of ARMS patients who enjoy favorable outcomes more consistent with ERMS; 20% of ARMS patients are fusion negative. A recent re-review of patients originally enrolled in the RMS study group D9602 focused on the outcomes of patients with ARMS that were fusion negative. The authors concluded that patients with low-risk features who were fusion positive should be treated on the intermediate-risk protocol, whereas those with fusion-negative features may be treated with lower intensity therapy (Arnold et al., 2016). In the current study ARST1431, patients with fusion-negative ARMS will be eligible for reduced therapy.

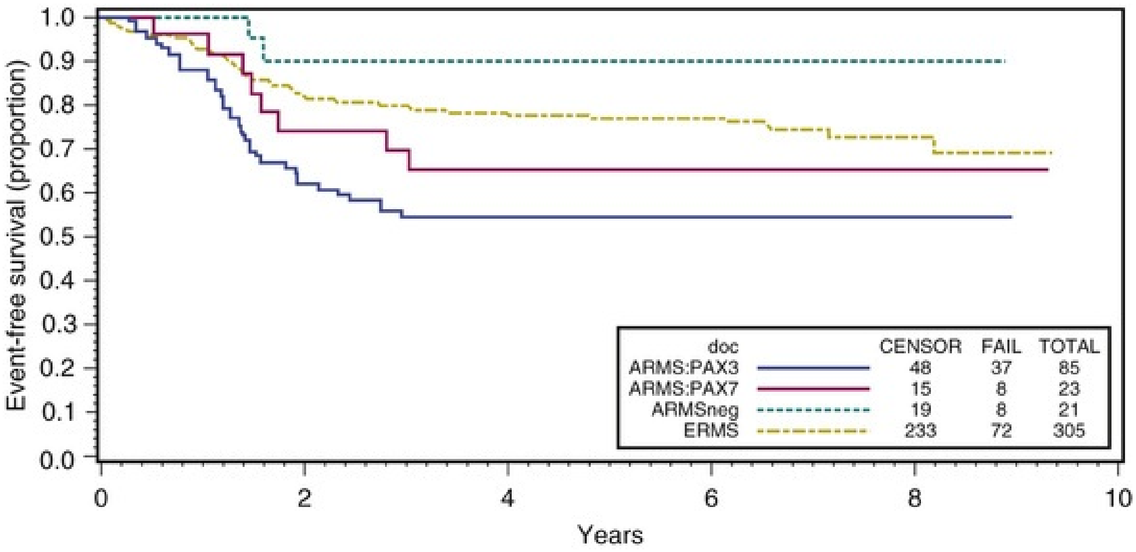

FIG. 54.2 Event-free survival of patients with alveolar rhabdomyosarcoma (ARMS) based on *PAX-FOXO1* fusion status compared with an embryonal RMS (ERMS) cohort. (Data from Skapek SX, Anderson J, Barr FG, et al.: *PAX-FOXO1* fusion status drives unfavorable outcome for children with rhabdomyosarcoma: a Children's Oncology Group report. *Pediatr Blood Cancer* 60:1411–1417, 2013.)

Studies are underway to understand the oncologic drivers downstream of these translocation proteins. Preliminary studies using genome-wide ChIP sequencing have identified transcriptional targets of *Pax3-FOXO1* protein such as fibroblast growth factor receptor 4 (FGFR4), which enhances proliferation and cell survival in ARMS; the insulin-like growth factor receptor 1 (IGF1R), known to stimulate myoblast growth; as well as another growth promoting gene, the c-Met receptor (c-Met) (Cao et al., 2010; Crose et al., 2012; Engert et al., 1996; Epstein et al., 1996; Ginsberg et al., 1998; Keller and Guttridge, 2013; Lagha et al., 2008). Finally, it appears that *Pax-FOXO1* fusion proteins can also disrupt the function of MyoD-regulated genes such as myogenin, p21, and muscle creatine kinase (Calhabeu et al., 2013).

Key Points

- Embryonal is the most common histology for bladder and prostate lesions.
- Alveolar histology is uncommon in the bladder or prostate.
- New studies indicated two distinct types of ARMS: PAX-FOXO1 fusion positive and negative; fusion-positive tumors carry a worse prognosis.

Presentation, Initial Evaluation and Management, Staging

Presenting Symptoms and Examination

It is estimated that 5% to 10% of all RMSs occur in the bladder or the prostate. The majority of these tumors are localized at presentation. Presenting symptoms commonly include urinary obstruction, urinary retention, urgency, frequency, and incontinence. Gross or microscopic hematuria occurs when the tumor breaks through the mucosal layer (Ferrer, 2010; Ferrer et al., 2006). On examination, a mass corresponding with a distended bladder or tumor may be palpated. Tumors within the bladder tend to grow intraluminally and are frequently botryoid in appearance. Rarely, tumors may prolapse into the urethra and be visible externally. Tumors of prostatic origin tend to be solid masses at presentation. Rarely are patients seen initially with evidence of systemic disease. Nodal drainage is to the pelvic nodes; thus they are typically not palpable (see Table 54.1).

TABLE 54.1

Nodal Drainage Patterns for Genitourinary Rhabdomyosarcoma

PRIMARY TUMOR SITE	NODAL DRAINAGE
Bladder/prostate	Pelvic and retroperitoneal nodes at or below renal arteries
Uterus/cervix	Pelvic and retroperitoneal nodes at or below level of renal arteries
Paratesticular	Pelvic and retroperitoneal nodes at or below level of renal arteries (inguinal nodes if scrotal skin is involved)
Vagina	Pelvic and retroperitoneal nodes at or below level of renal arteries
Vulva	Inguinal nodes
Retroperitoneum/pelvis	Pelvic and retroperitoneal nodes
Perianal/perineal	Inguinal and pelvic nodes; may cross midline

Data from Scarpato KR, Ferrer FA, Rodeberg DA, et al.: Genitourinary rhabdomyosarcoma in children. *AUA Update Series* volume 32, lesson 9, 2013.

Key Point

- Bladder/prostate tumors typically are accompanied by symptoms of obstruction, retention, or hematuria.

Evaluation

Abdominal/pelvic ultrasonography (US) is commonly the first study in children with hematuria or obstructive symptoms. When a mass lesion is suspected, definitive imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is indicated. The site of origin, prostate versus bladder, can be difficult to ascertain. The pelvic nodal basin of the bladder/prostate tumors should be assessed using fine-cut CT or MRI. CT of the chest is required to exclude pulmonary metastasis (the most common site). Bone scan, bone marrow biopsy, and aspirates are also indicated; however, recently, a reduction in staging investigations for patients with translocation-negative disease has been recommended by the COG.

A recent analysis of ERMS and ARMS patients demonstrated that patients with ERMS who have tumors that are less than 5 cm and noninvasive (T1), without nodal disease, had a 0 chance of having bone or bone marrow metastases. Thus patients with ERMS without nodal or lung metastases do not require bone scans or bone marrow evaluations (Weiss et al., 2013). Any metastatic sites must be identified for appropriate treatment selection. Growing evidence suggests a role for positron emission tomography CT (PET-CT) in staging and monitoring disease response. Tateishi et al. have suggested that TNM stage and post-treatment restaging were more accurately described by PET-CT than by conventional imaging (Federico et al., 2013; Tateishi et al., 2009). The current intermediate-risk protocol evaluates the role of fluorodeoxyglucose (FDG)-positron emission tomography (PET) imaging in RMS patients.

Biopsy Techniques and Management of Obstruction

Biopsy for definitive diagnosis can be challenging. The limited size of pediatric resectoscopes and narrow width of hot loupes make adequate endoscopic biopsy difficult. Circumscribing a section of a polypoid tumor using cutting current and then subsequently removing the section intact with biopsy forceps can aid in obtaining an adequate sample (Snyder, 2005). Excessive use of cautery can lead to cautery artifact, which may mimic spindle cells. Coordination with an experienced onsite pathologist is essential to evaluate frozen sections. **If adequate tissue for diagnoses cannot be obtained endoscopically, COG protocols recommend open transvesical biopsy with pelvic and para-aortic lymph node sampling.**

Patients may require management of lower or upper urinary tract obstruction at presentation. **Early and effective management of obstruction is essential in these patients to maximize renal function, which will be taxed by systemic therapy.** As a general rule I prefer placement of a urethral catheter above a suprapubic tube for bladder outlet obstruction. In my experience, response to therapy may be rapid, and the catheter can be removed in a few weeks. Ureteral obstruction is best managed using indwelling ureteral catheters. If these cannot be placed in a retrograde fashion, percutaneous nephrostomy tube placement with conversion to internal catheters may be considered (Meir et al., 2004).

Staging and Childrens Oncology Group Risk Group Assignment

Staging patients with RMS is complex and involves the use of a pretreatment TNM staging system, a post-biopsy or resection surgical-pathological group system, and finally, risk group stratification (low, intermediate, high), which is derived from the TNM and surgical-pathological group systems (see Tables 54.2 through 54.4). The pretreatment TNM system sorts patients into favorable and unfavorable sites. Favorable sites for genitourinary (GU) RMS include para-testicular, vulvar-vaginal, and uterine tumors. Bladder/prostate (B/P) tumors arise from an unfavorable site (see Table 54.2). Local stage, tumor size, histology, nodal status, and metastasis are also considered in the pretreatment stage. The surgical-pathological group score is affected by the presence of residual disease. With the advent of organ preservation strategies, more patients undergo initial biopsy in lieu of resection, which has shifted the majority of B/P RMS patients from group I to group III (see Table 54.3). Patients are then stratified into low-, intermediate-, and high-risk groups. B/P RMS patients are commonly intermediate risk (see Table 54.4). Patient age is another independent prognostic factor: patients younger than 1 year and older than 10 years have inferior survival rates (Joshi et al., 2004; Meza et al., 2006). **The ARST1431 study will be the first sarcoma study to use FOXO1 fusion status rather than histology for study eligibility, because it is more predictive of outcome**

as demonstrated by several independent analyses (Furlong et al., 2001; Skapek et al., 2013).

TABLE 54.2

Intergroup Rhabdomyosarcoma Study Group Pretreatment TNM Clinical Staging

Stage 1: Favorable site, nonmetastatic Stage 2: Unfavorable site, small tumor, negative nodes, nonmetastatic Stage 3: Unfavorable site, larger or positive nodes, nonmetastatic Stage 4: Any site, metastatic
TUMOR
T1: Confined to site of origin ≤5 cm 5 cm T2: Fixation to surrounding tissues ≤5 cm >5 cm
SITE
Favorable: Orbit, nonparameningeal head and neck sites, male (paratesticular) or female (vagina, vulva, cervix, or uterus) genital tracts ***Unfavorable:*** All other locations (e.g., bladder and prostate)
REGIONAL LYMPH NODES
N0: Regional lymph nodes not clinically involved N1: Regional lymph nodes clinically involved

Localized disease, completely resected
GROUP II
Grossly resected tumor with microscopic residual disease Regional disease with involved nodes, completely resected with no microscopic residual Regional disease with involved nodes, grossly resected, but with evidence of microscopic residual and/or histologic involvement of the most distal regional node (from the primary site) in the dissection

GROUP III
Incomplete resection or biopsy with gross residual mass
GROUP IV
Distant metastasis

Data from Scarpato KR, Ferrer FA, Rodeberg DA, et al.: Genitourinary rhabdomyosarcoma in children. *AUA Update Series* volume 32, lesson 9, 2013.

TABLE 54.4

Rhabdomyosarcoma Risk Stratification

HISTOLOGY	CLINICAL GROUP	STAGE	AGE	RISK GROUP
Embryonal, with variants	I, II, III	1	All	Low
Embryonal, with variants	I, II	2, 3	All	Low
Embryonal, with variants	III	2, 3	All	Intermediate
Embryonal, with variants	IV	4	<10 yr	Intermediate
Embryonal, with variants	IV	4	≥10 yr	High
Alveolar	I, II, III	1, 2, 3	All	Intermediate
Alveolar	IV	4	All	High

Treatment and Outcomes

Evolution of Multimodal Treatment

Advances in the treatment of RMS have been facilitated by collaborative groups, including the COG (encompassing the Intergroup Rhabdomyosarcoma Study [IRS]), the International Society for Pediatric Oncology (SIOP), the Italian Cooperative Group (ICG), and the German sarcoma study group, Cooperativen Weichteilsarkom Studie (CWS). At the initiation of IRS-I (1972–1978), treatment of B/P RMS involved radical surgery (Ferrer et al., 2006; Horn and Enterline, 1958). The combination of upfront surgery with adjuvant chemotherapy resulted in an OS of 78% with significant associated morbidity related to extirpative surgical procedures (Ferrer and Ritchey, 2006; Raney et al., 1993).

IRS-II (1979–1984) and SIOP RMS 75 were the first to use neoadjuvant chemotherapy and radiation and focus on bladder preservation. Ten percent of patients achieved relapse-free survival with chemotherapy alone. OS was 80%, but the functional bladder preservation rate was still only 25% (Crist et al., 1995; Raney et al., 2001). In IRS-III (1985–1992) the use of doxorubicin, cisplatin, and etoposide coupled with radiotherapy saw OS for BP/RMS rise to 83% and bladder preservation rates go up to 60% (Crist et al., 1995; Hays et al., 1995, Lobe et al., 1996; Raney et al., 2001). In IRS-IV (1993–1997) pretreatment TNM staging and a regimen of vincristine, dactinomycin, and cyclophosphamide were used. Arndt et al. (2004) reported on the IRS-IV outcomes for patients with B/P RMS. At 6.1 years EFS was 77% and OS was 82% (Arndt et al., 2004), but only 36 (40%) of the original 88 patients are failure free with “normal” bladder function.

IRS-V was the first protocol to use risk stratification. The 3-year failure-free survival rate was 88% for low risk, 76% for intermediate risk, and less than 30% for high-risk patients (Alexander et al., 2012; Ferrer and Ritchey, 2006; Ferrer et al., 2006). Little change has occurred in survival in subsequent studies.

Current Multi-Model Approaches: Children's Oncology Group

The majority of B/P patients have tumors that are unresectable at presentation and therefore undergo diagnostic biopsy, as opposed to an upfront primary excision that could compromise organ function. If resection is attempted as a primary procedure (e.g., a bladder dome lesion), or later in the patient's course as a secondary procedure (rare), surgeons should mark any area outside the bladder lumen, suspicious for residual disease with titanium clips, because frozen section margins may be unreliable. Patients undergo imaging of the appropriate nodal drainage pathways (see Table 54.1). Pathological confirmation of any radiographically positive nodes should be performed to avoid unnecessary radiotherapy. If a patient has suspicious nodes, open bladder and concomitant pelvic and para-aortic nodal biopsy may be preferred.

COG protocols advise that complete response to nonoperative therapy (chemo/radiation) may not be rapid and that radical surgery should be avoided. A residual mass does not always represent viable tumor. Tumors cells may involute, leaving a mass that consists primarily of surrounding stroma. They may also differentiate into mature rhabdomyoblasts that do not require radical resection (Wu and Snyder 2004; Wu et al., 2009). **Further, residual mass does not correlate with outcome.** IRS-III highlighted this fact, showing that 36% of patients without radiologic response to nonoperative treatment were in complete remission based on pathological assessment of resection specimens (Hays et al., 1995; Raney et al., 2001).

After diagnostic biopsy patients proceed to the appropriate risk-stratified treatment regimen, which, in the current study involves chemotherapy, surgery, and radiation therapy. The only open COG study as of this writing is the intermediate-risk study, which is most relevant to B/P RMS patients. The objectives of the current COG intermediate-risk study ARST1431 are to

1. Compare EFS and OS of patients treated with surgery, radiotherapy, and vincristine, adriamycin, and cyclophosphamide (VAC), alternating with vincristine and irinotecan (VI) to that of patients in which temsirolimus (mTOR inhibitor) has been as added to the treatment regimen.
2. Compare survival of patients based on their FOXO1 fusion gene partner (*PAX3* vs. *PAX7*).
3. Assess response at 9 weeks of therapy using FDG-PET as a predictor of outcome.
4. Estimate the frequency of patients with circulating tumor DNA at diagnosis and subsequent therapeutic time points.

Specifics regarding local control measures in this study are delineated in the local control section that follows. Study protocols are available through each participating institution's principal investigator and have detailed surgical guidelines.

Key Points

- Organ preservation is a principal goal of treatment; therefore most patients treated in COG protocols undergo endoscopic/open biopsy as the initial step.
- Pretreatment TNM staging and a surgical-pathological group classification contribute to the patients’ final risk group assignment, which, in turn, determines therapy.
- New to the current study is the use of fusion status for therapeutic group assignment.
- Bladder/prostate tumors arise from an unfavorable site and gross residual tumor usually remains after biopsy; therefore most patients are assigned to the intermediate-risk group.
- A residual mass after chemotherapy and radiotherapy does not necessarily

mean viable tumor remains.

- Rhabdomyoblasts are differentiated tumor cells that do not require further treatment.

Current Multi-Model Approaches: European Cooperative Groups

SIOP's philosophical approach to B/P RMS has varied from that of IRS and later COG. Although both groups have focused on bladder preservation, the SIOP MMT 84, 89, and 95 (1984–2003) studies have taken a fundamentally different view on local control, avoiding radiation. Patients are treated with chemotherapy and assessed for response (Flamant et al., 1985; Oberlin et al., 2012; Stevens et al., 2005). Patients enrolled in MMT 89 also received ifosfamide, vincristine, and dactinomycin (IVA) as primary therapy, and in MMT 95 patients were randomized to receive either IVA or a 6-drug regimen consisting of ifosfamide, vincristine, actinomycin D, carboplatin, epirubicin, and etoposide. Tumor response is evaluated radiographically and endoscopically. Patients not exhibiting complete response are considered for conservative surgery (tumorectomy, partial cystectomy, or prostatectomy). Radiotherapy is used only in cases in which a cure is not achieved by chemotherapy and surgery. If necessary, radical surgery is considered, as opposed to external beam radiotherapy (ERT), to avoid the late consequences of ERT (Flamant et al., 1985; Oberlin et al., 2012; Stevens et al., 2005).

Using this approach SIOP recently reported the combined results for MMT 84, 89, and 95 (Jenney et al., 2014). In all, 175 patients were eligible for analysis. Key outcomes included EFS and OS, which were 63% and 77%, respectively. Although the 5-year OS was similar to that of other international groups, the EFS was lower than that reported by COG. It is assumed that the lower EFS is related to the diminished use of radiotherapy in these trials. The similar OS may reflect the ability to “recover” some of these patients with second-line therapy. The percentage of preserved bladders increased from 69% to 73%, and most recently in MMT 95, to 76% (Jenney et al., 2014). Similar to SIOP protocols, the reported Italian Cooperative Group (ICG) studies ICG-79 and ICG-88 focus on upfront 3-drug chemotherapy and attempted to avoid radiotherapy. EFS and OS results were not significantly different from those observed in SIOP studies (Rodeberg et al., 2011).

Results from the CWS study, CWS-96, were reported in 2011 (Seitz et al., 2011). Patients were biopsied and then went on to receive neoadjuvant chemotherapy with 3 drugs. Radiologic response after 9 weeks determined local therapy. Patients with complete response did not receive radiotherapy, those with more than two-thirds response received 32 Gy, and those with less than two-thirds response received 45 Gy. Primary resection was discouraged unless it would not affect bladder function. Secondary surgery was performed only if residual disease remained after radiotherapy. A total of 63 patients were analyzed. Radiation was given to 60.3%; 51 underwent upfront biopsy, and only 12 had primary resection. Secondary resection was performed in 45 patients. The 5-year OS for the entire group (all stages) was 76.3%. Patients having only chemoradiotherapy had an OS of 87.5%. Patients who had chemotherapy and surgery had an OS of 84% as compared with those undergoing chemo-radiation followed by tumor resection in 87.8%. Those undergoing incomplete resection with follow-up radiotherapy and chemotherapy had an OS of only 39% (Seitz et al., 2011). The follow-up study to CWS-96 was the CWS 2002P trial, for which results were reported in 2016. The treatment protocol was similar to CWS-96; 42 B/P RMS patients were evaluable, the 5-year OS was 84.5%, and EFS was 79.9%. The bladder preservation rate was 80.9%. Although not statistically different, the results are somewhat improved from CWS-96, presumably because of fewer protocol violations and lower use of radiation. Patients with large tumors greater than 10 cm had a poor 5-year EFS (50%). The 5-year OS for 6 patients with local relapse was only 33% (Seitz et al., 2016a,b).

In summary, all of the cooperative groups have focused on bladder preservation. Overall survival results between the two different approaches are similar. Protocols avoiding radiotherapy appear to have lower EFS but comparable OS, suggesting that children who fail can be rescued with intensified chemotherapy. Survival for B/P RMS has not changed substantially in two decades. It is likely that novel therapies or an enhanced understanding of risk stratification, perhaps based on genomic analysis, will be required before we see further improvement (Rodeberg et al., 2011).

Local Control

How to best attain local control in RMS patients has been a subject of intense discussion. Approaches have involved surgery, radiation therapy, or the combination of both. Both modalities have the potential for significant side effects. The concern regarding radiation late effects has prompted our European colleagues to use XRT very selectively (Dantonello et al., 2009). In study D9803 radiation dosage was based on the size of the residual mass at 12 weeks: the minimum dose was 36 Gy and the maximum dose was 50.4 Gy. For patients with group III disease the local recurrence rate was 19%, for those with bladder prostate lesions specifically, that number was 14%. The only clear predictor of local recurrence was initial tumor size exceeding 5 cm (25% vs. 10% for those under 5 cm).

The current COG intermediate-risk study (ARST1431) addresses local control with 2 approaches. The first delayed primary excision (DPE) allows for patients to undergo resection at 12 weeks post-initiation of chemotherapy when appropriate (debulking operations or procedures that would compromise organ functionality are not indicated). Patients who had a gross total resection may qualify for reduced-dose radiation. The second strategy involves increasing radiation for tumors exceeding 5 cm at presentation. Specifically, in the current study a total dose of radiation of 59.4 Gy is recommended for primary tumors exceeding 5 cm for those patients who will not undergo DPE.

Treatment of Very Young Children

Because of their increased susceptibility to treatment-related morbidity, management of infants with B/P RMS is a significant challenge, and age less than 1 year remains an adverse prognostic factor (Crist et al., 2001; Joshi et al., 2004; Malempati et al., 2011). Various collaborative groups have demonstrated significantly lower failure-free survival in infants (Ferrari et al., 2003; Joshi et al., 2004; Malempati et al., 2011). Because there is no clear evidence that the biology of RMS is different in young children, it is thought that reduction in prescribed therapy is responsible. Specifically, studies by Ragab et al. (1986) and Malempati et al. (2011) have demonstrated higher local failure rates for infants treated in IRS studies. These higher local failure rates have been associated with a reduction in recommended radiation therapy (Ferrari et al., 2003; Malempati et al., 2011). Puri et al. (2006) evaluated a population of 20 infants and toddlers receiving external beam radiotherapy, 7 of 20 experienced long-term morbidity, including altered ambulation, recurrent infections, and second malignant neoplasms. COG protocol allows the treating institution to deviate from protocol-prescribed radiation therapy for children younger than 24 months of age who are FOXO1 fusion negative. The issue of appropriate therapy for very young children remains unresolved.

Timing of Surgical Reconstruction

Although bladder preservation rates have risen, some cases still require extirpative surgery. In these instances, the appropriate timing for reconstruction is a central question. Several authors have suggested that it is feasible to perform reconstruction concomitantly with cystectomy or cystoprostatectomy. Lander et al. (1992) described performing immediate “le bag” neobladder reconstruction on 3 children undergoing cystectomy for RMS. The reconstructive procedures themselves were successful and initial frozen sections of margins were negative. However, viable tumor was present on permanent sections, mandating further chemotherapy and radiotherapy to the reconstructed pelvis (Lander et al., 1992). Similarly, Merguerian et al. (1998) noted that frozen section proved unreliable in predicting residual disease. Hensle and Cheng (2000) observed that, although early reconstruction is feasible, it should be considered carefully and avoided if further local therapy is a possibility. The group from Padua, Italy, published their experience with continent orthotopic reconstruction using the “VIP” bladder (Castagnetti et al., 2013). Of 9 patients undergoing urethral preservation, 2 experienced local recurrence despite negative intraoperative frozen section and permanent section evaluation. Contrasting this experience is that of the Mainz group (Stein et al., 2013). Their preference is to perform continent reconstruction at the time of cystectomy. From a group of 25 patients, 11 underwent continent cutaneous diversion and 2 underwent a urethral ileocecal pouch. All of these patients are reported to be continent, and none appear to have had local recurrence (Stein et al., 2013).

The difficulty in predicting local recurrence and concerns related to irradiating the recently reconstructed GU tract has prompted some to advocate for delayed reconstruction. Duel et al. (1996) performed initial urinary diversion followed by delayed reconstruction in those patients obtaining long-term cure. They used colonic segments to create a temporary conduit, avoiding the previously irradiated ileum. These segments were later reconfigured into the cutaneous continent reconstructions. Experience with delayed orthotopic reconstruction is limited. Recently the group from Padua described their disappointing continence results in 2 patients in which this approach was attempted (Castagnetti et al., 2013). **In conclusion, early reconstruction is feasible; however, the inaccuracy of intraoperative margin analysis increases the likelihood of positive margins, local tumor recurrence, and further local therapy in a reconstructed pelvis.**

Outcomes

In the most current large report the outcomes of patients from IRS/COG, SIOP, ICG, and CWS are reviewed collectively and comparatively (Rodeberg et al., 2011). In all, the outcomes of 379 patients were evaluated. Patients aged birth to 5 years made up 74% of the cohort; 87% were younger than age 10; 82% were male. Analysis of pathology revealed that 322 of 379 (85%) had localized embryonal tumors. Metastases were observed in only 7% of patients with ERMS. Thirty patients (8%) had nonembryonal pathology (alveolar or other). The site of origin was recorded as bladder 59%, prostate 29%, or bladder or prostate 12% (Rodeberg et al., 2011). Prognostic features included local tumor invasion, tumor size, and histology. In evaluation of the treatment of localized B/P RMS patients, 48% of SIOP/ICG received radiotherapy versus 85% of patients enrolled in IRS/CWS.

The collective outcomes demonstrated a 5-year failure-free survival of approximately 75% for patients with localized tumors. The 5-year OS was 84%. The majority of failures (88%) occurred within 3 years. The location of failures was local 60%, regional nodes with or without local disease 9%, and 25% with distant failure with or without local disease (Rodeberg et al., 2011). **Comparative outcomes analysis of collaborative group protocols revealed no statistically significant difference between the groups in FFS or OS when correcting for tumor invasion and tumor size between the groups** (Rodeberg et al., 2011).

The last fully reported IRS/COG results come from IRS-IV. Eighty-eight patients were included in the analysis. The OS at 6 years was 82%, the EFS was 77%. Fifty-five patients retained their bladders, but only 36 (40%) reported normal bladder function (Arndt et al., 2004). Functional bladder evaluation was limited in this study. In 2006 an international workgroup reported on continence of 62 patients, age 6 or older who did not undergo cystectomy. Forty-three (69%) were reported to be continent, 16 had nocturnal incontinence, and 9 had diurnal incontinence. Patients undergoing partial cystectomy had a continence rate of 73%. Of the entire group only 11 underwent formal urodynamic study (Raney et al., 2006). The oft-cited series by Yeung et al. (1994) reports on 11 patients undergoing complete urodynamic evaluation after cure for pelvic RMS. In this report only children who did not receive RT had normal bladder function. Similarly, Hays et al. (1995) observed that patients receiving radiation were more likely to have adverse bladder functional sequela and that a dose effect was present; those receiving 40 Gy or higher had more complications.

Another important question remains: What is the outcome of children who require salvage surgery? The question was addressed in a recent report from the 28-year Italian experience. Of the 108 patients enrolled in their protocols, 33 (30.6%) underwent “salvage” surgery, of whom 26 patients had more than 5 years of follow-up. For these patients the authors found that the most significant predictor of EFS was tumor differentiation within the resected specimen. Undifferentiated tumors had a statistically significant poorer outcome as measured by progression-free survival at 5 years. Undifferentiated histology increased the odds of failure 28 times. Interestingly, positive tumor margins did not correlate with outcomes in this study (Angelini et al., 2016).

In summary, OS continues to be relatively unchanged for more than 2 decades in patients with B/P RMS. Molecular staging will hopefully lead to more appropriate staging and appropriate treatment burdens. The true long-term success of bladder preservations strategies remains somewhat unclear.

Late Effects

The treatment of RMS at any pelvic site is associated with potential short- and long-term morbidity. Relative to fertility and sexual function, Raney et al. (2006) analyzed the urologic complications of 164 patients treated for B/P RMS from an international cohort. Unfortunately, data were available for only 35 (21%) of the patients. After treatment for B/P RMS 25 men were potent and 2 were impotent. Sixteen had preserved ejaculation and 4 suffered from anejaculation. Two of 7 females with available data had abnormal menses (Raney et al., 2006). Mansky et al. (2007) used a questionnaire and serum analysis to evaluate survivors of pediatric sarcoma. Of 13 female participants, 7 (47%) became pregnant, 6 remained premenopausal, and 7 experienced premature menopause. With regard to male fertility, only 4 of 17 (24%) fathered children. Among those who did not father children, 9 consented to semen analysis for the study. Six of these were azoospermic, 2 had oligospermia, and 1 was normal; thus only 29% were fertile based on history or semen evaluation. All 3 males who received pelvic XRT were infertile (Mansky et al., 2007). Frees et al. (2016) reported on 13 males undergoing RMS treatment between 1975 and 2014. Patients were studied using the erection hardness score (EHS) and the self-estimation index of erectile function–no sexual intercourse (SIEF-NS). Three patients demonstrated no impairment; none of these patients had undergone radiotherapy; radical cystoprostatectomy had been performed in 2 before age 3. The rest of the patients had erectile dysfunction. Patients who failed oral PDE-5 therapy were successfully treated with alprostadil (Frees et al., 2016). Spunt et al. (2005) reviewed the 20-year late effects of female survivors of pelvic RMS. Delayed morbidity was found in 24 of 26 patients. Of the whole group, 77% had endocrinologic/ovarian dysfunction, and 58% experienced gynecologic dysfunction, including absence of a uterus, ovaries, or vaginal stenosis. **Although large detailed studies are lacking, it is clear that significant reproductive and sexual functional consequences occur with current treatments** (Armstrong et al., 2014).

Bladder function may be impaired as a result of surgery, chemotherapy, or radiation. **Arndt's review of outcomes from patients in IRS-IV suggests that despite bladder preservation strategies, more than 60% of patients have some degree of bladder dysfunction.** Only 3 studies have used the “gold standard,” urodynamics, to evaluate treatment. Yeung et al. (1994) evaluated 11 children treated for pelvic sarcoma. Seven patients received ERT or brachytherapy, and all of them experienced decreased bladder capacity and irritative symptoms. Soler et al. (2005) evaluated 8 children undergoing multimodal therapy. Five of them experienced dysuria, urgency, frequency, and diminished capacity. More recently, Martelli et al. (2016) evaluated 11 children post-treatment with urinary dysfunction; the most common finding was detrusor sphincter dyssynergia.

An increased risk of second malignant neoplasm is associated with radiotherapy and chemotherapy. Studies of pelvic RMS survivors suggest that they develop secondary malignant disease at 6 times the normal rate (Cohen et al., 2005). Mansky et al. (2007) reported second malignancies including osteosarcoma, Ewing sarcoma, and T-cell lymphoma in 9% of patients treated for pelvic sarcoma. Osteosarcoma, colon adenocarcinoma, and cervical squamous cell carcinoma were among the second malignancies experienced in Spunt's series of 26 survivors (Spunt et al., 2005). International cooperative groups have validated these findings (Bisogno et al., 2012). **Long-term monitoring of B/P RMS patients in specialized survivorship clinics is recommended.**

Oncofertility

Just under 16,000 children were diagnosed with cancer in 2016. As survival rates have increased, so have long-term effects of treatment (CureSearch Institute, NC). Future fertility is adversely affected in males and females by cancer treatment. The risk of infertility increases with the cumulative dose of alkylating agents and radiation affecting the gonads (Ginsberg, 2011). Males are vulnerable to gonadotoxicity from chemotherapy at all ages; females, on the other hand, are relatively protected in the prepubertal period. Radiotherapy affects male and female fertility. In prepubertal males 6 grays (Gy) is enough to result in permanent azoospermia; the threshold drops to 2.5 Gy in postpubertal males. In prepubertal females threshold doses for infertility are more than 15 Gy and more than 10 Gy in postpubertal girls. Females undergoing cranial or spinal radiation are also at risk because of the scatter effect on the ovaries. Patients undergoing myeloablative therapy and subsequent bone marrow transplant are also at high risk (CureSearch; Green et al., 2014a,b).

Despite the fact that multiple societies have released guidelines regarding fertility preservation in prepubertal children and adolescents, many patients are not adequately counseled before treatment, and studies have shown racial and other demographic bias can affect access (Practice Committee of American Society for Reproductive Medicine, 2013). In postpubertal males semen cryopreservation is an accepted modality for preservation of fertility. Although there are potential psychological and physical barriers involved, it is a technique that is well understood and widely available. The overall success rate of sperm banking is unclear. A multicentric study from a sperm-banking cooperative in France demonstrated that more than 4300 young cancer patients visited a fertility clinic, and 93% were able to provide a sample; 3616 (83%) provided enough material to allow sperm to be cryopreserved. Conversely, a UK study (180 patients) yielded less optimistic results, with only 66% of the patients being able to bank sperm; azoospermia was found in 13% (Daudin et al., 2015; Keene et al., 2012).

For prepubertal boys limited options exist: tissue retrieval at this time is unlikely to generate cells that can be used for assisted reproduction techniques. The counterarguments are that these patients will not be interested in fathering children for decades and that novel techniques are evolving. In fact, Yokonishi et al. (2014) have reported successful pregnancy in a murine model using neonatal testicular tissue with in vitro induction of spermatogenesis. Viable offspring were produced, and they, in turn, were able to produce progeny of their own. Options to preserve female fertility include radiation shielding, ovarian transposition, oocyte cryopreservation, embryo cryopreservation, and ovarian tissue cryopreservation. Gonadotropin-releasing hormone analogues have not proven effective in pediatric patients (Burns et al., 2018).

In postpubertal females, embryo cryopreservation and oocyte cryopreservation is standard of care as per the American Society for Reproductive Medicine. Both techniques involve ovarian stimulation follicular monitoring using ultrasound and subsequent transvaginal oocyte retrieval under sedation or anesthesia (Practice Committee of American Society for Reproductive Medicine, 2013). The only preservation option for prepubertal females is ovarian tissue cryopreservation (OTC). In this technique ovarian tissue or the complete ovary is harvested laparoscopically. The tissue is evaluated to exclude malignant tissue, and the ovarian cortex is harvested and cryopreserved. Clinical pregnancy rates in excess of 50% have been reported with this technique (Burns et al., 2018). Finally, ovarian tissue transplantation (OTT) involves thawing and then transplanting orthotopically or heterotopically ovarian cortex to patients. This is the only technique that can restore hormonal function to women and has been reported to be successful in some patients who were prepubertal at harvest (Demeestere et al., 2015).

Other Bladder Tumors

Transitional Cell Carcinoma

Transitional cell carcinoma (TCC) of the bladder is an uncommon lesion in children and adolescents. In a review of 10,000 cases of bladder epithelial tumors performed by Javadpour and Mostofi (1969) only 38 cases of TCC occurred in patients younger than 20 years of age. A more recent review indicated that there are about 125 cases reported in patients younger than age 20, only 20 of which are in patients younger than 10 years old (Lerena et al., 2010). A male-to-female preponderance of 3-9 : 1 exists (Hoenig et al., 1996; Lerena et al., 2010). Unlike adult tumors, which have been associated with environmental exposures and smoking, the cause in children remains unclear. Familial history or genetic conditions have not been associated with pediatric cases (Lerena et al., 2010). Cyclophosphamide treatment and more recently chronic exposure to dantrolene have been cited as possible causes (Dowling et al., 2007; Hoenig et al., 1996).

The most common presenting symptom is gross hematuria, although symptoms of bladder irritation and UTI have been noted. The diagnosis is frequently delayed in children and is often discovered when US detects a lesion. It has been postulated that US approaches 100% sensitivity and is the preferred method for surveillance (Hoenig et al., 1996; Serrano-Durba et al., 1999). Voiding cystourethrogram is less sensitive because dye density may obscure the tumor (Lerena et al., 2010). The definitive diagnosis is made by cystoscopy and biopsy. The majority of lesions (75%) occur in the trigone and are unifocal, although multifocal lesions have been reported (Hoenig et al., 1996; Khasidy et al., 1990; Quillin and McAlister, 1991; Serrano-Durba et al., 1999). The overwhelming majority of lesions (80%) are superficial, low-grade lesions. A small portion of lesions are high grade. A recent study suggests that higher-grade lesions are associated with increasing age (Caione et al., 2017). A single case of invasive disease leading to death has been reported (Hoenig et al., 1996; Paduano and Chiella, 1988; Scott et al., 1989). Pediatric TCC is best treated with transurethral resection; intravesical therapy has had no defined role.

Typically pediatric bladder TCC does not involve the upper tracts; therefore no recommendations for routine upper tract surveillance exist (Vikram et al., 2009). Recurrence appears to be rare, even when higher-grade lesions have been reported (Lerena et al., 2010). Periodic surveillance with ultrasound is recommended, because it is sensitive in this scenario, obviating the need for serial cystoscopy. I perform US every 3 months for 1 year, every 6 months for the second year, and annually thereafter. No guidance exists regarding timing for discontinuing evaluation.

Cancer in the Augmented Bladder

Concern that patients undergoing urinary diversion were at risk for cancer began with the ureterosigmoidostomy experience (Husmann and Spence, 1990). It was assumed that by separating urinary and fecal streams, augmentation could avoid these complications; however, reports of cancer in patients with augmented bladders raised concerns anew (Filmer and Spencer, 1990; Gittes, 1986; Golomb et al., 1989; Nurse and Mundy, 1989). Recommendations for annual endoscopic screening for patients beginning 5 to 10 years after reconstruction followed. **These recommendations have recently been critically re-evaluated in light of 2 observations:**

1. **The majority of reported cases come from a patient pool biased toward infectious causes; few data on risk in patients augmented for noninfectious causes are available** (Filmer and Spencer, 1990; Golomb et al., 1989; Kamyshan et al., 2000).
2. **Patients with congenital bladder abnormalities related to exstrophy complex and spina bifida have a higher basal incidence of cancer than the normal population** (Austin et al., 2007; Barrington et al., 1997; Beare et al., 1956).

Husmann and Rathbun (2008) studied augmented patients compiled within a registry using the following criteria:

1. Minimum follow-up interval was 10 years.
2. No patient ever had a form of urinary diversion in which a mixture of feces and urine had occurred.
3. Patients with a history of bladder exstrophy/epispadias complex could be included only if they had undergone bladder closure within the first 2 weeks of life.
4. Only patients augmented secondary to neurogenic bladder or

exstrophy/epispadias complex or as a consequence of PUV were included.

Of the patients enrolled, 7/153 (4.5%) developed cancer; the median time to development of a tumor was 32 years. Bacteriuria did not correlate with the development of tumor. Incidence between ileal and colonic augments was not markedly different. Two patients augmented for neurogenic bladder developed multifocal TCC in their native bladder, but both had prolonged tobacco exposure. Twelve percent of patients augmented for PUV developed adenocarcinoma of the augmented bladder. Notably, all had ESRD, had undergone transplant, and were immunosuppressed. **The authors commented that patients with a smoking history after augmentation or those with ESRD, transplantation, and immunosuppression appear to be at greatest risk** (Husmann and Rathbun, 2008).

Higuchi et al. (2010) compared 153 patients who had undergone ileal/colonic augmentation with age- and disease-matched controls without augmentation to determine if an increased cancer risk was present. The authors documented no statistically significant increase in bladder cancers in augmented vs. nonaugmented patients (4.6% vs. 2.6%). Their data suggested that patients with neurogenic bladder have a baseline increase in cancer rates. They also supported the concept that exstrophy-epispadias patients are also at an increased risk. Again, an increase risk of cancer was present in immunosuppressed patients with a history of opportunistic viral infection (Higuchi et al., 2010).

Regarding surveillance, Higuchi et al. (2011) evaluated the utility of annual cytology and endoscopy. The authors found cytology was not helpful because of a significant false-positive rate. The authors also noted that only 4 of 250 surveillance cystoscopies revealed suspicious lesions, none of which proved cancerous. Based on the current estimated rate of malignant transformation of 1.5% to 2.8% the authors concluded that more than 980 cystoscopies would have to be performed over a decade to diagnose 1 tumor. Endoscopy was recommended only in the following circumstances (Higuchi et al., 2011):

1. Four or more symptomatic urinary tract infections (UTIs) occur per year.
2. A history of gross hematuria and/or urinalysis with greater than 50 RBCs/hpf is present.
3. Chronic perineal, pelvic, or bladder pain occurs.
4. Abnormal radiographic screening studies are seen.

5. Patients with colon augments turn age 50 years or older, consistent with recommendations for colonoscopy.

Similarly, using Markov model analysis, Kokorowski et al. (2011) concluded that annual cytology and endoscopy were not cost effective and questioned their effectiveness overall. A recent literature review suggests that no survival difference exists between spina bifida patients with bladder cancer based on whether they have been augmented (Rove et al., 2017).

In summary, it appears that the risk of cancer after augmentation may have been overstated. Augmented patients who are immunosuppressed after transplantation or perhaps those with a tobacco history may be in a higher risk group. The efficacy of annual cystoscopy and cytology appears questionable.

Urachal Carcinoma

Urachal adenocarcinomas in children are exceedingly rare (Rankin et al., 1993). A retrospective review of medical records from the Mayo Clinic from 1951 to 2005 identified no malignancies among urachal remnants in children (Ashley et al., 2007). Recently, a mucinous carcinoma of the urachus was reported. The lesion was managed by complete surgical excision (Gupta et al., 2014).

Adenocarcinoma and Squamous Cell Carcinoma

Patients with bladder exstrophy are considered to be at increased risk for adenocarcinoma. In a recent review of augmented patients 3 of 38 (8%) developed adenocarcinoma involving the bladder and an augment bowl segment. The site of origin could not be determined, and all patients fared poorly. These findings are consistent with prior publications, suggesting an increased risk of adenocarcinoma, squamous carcinoma, or tumors of mixed cell types in extrophy patients (Beare et al., 1956; Sahai et al., 2004; Smeulders and Woodhouse, 2001; Woodhouse et al., 2006). The belief that early closure may diminish the rate of malignancy in exstrophy patients does not appear to have held up: all 3 exstrophy patients within Hussmann's series had early closure (Husmann and Rathbun, 2008). Squamous cell carcinoma (SCC) has also been reported in exstrophy patients (Patil et al., 2012). It appears that the most common scenario is that of tumors occurring in patients with exposed bladders.

In the absence of exstrophy or schistosomiasis, SCC in the pediatric population is exceedingly rare: the youngest reported patient was a 16-year-old with a history of bladder calculus (Sung and Koyle, 2000).

Benign Bladder Tumors

Inflammatory myofibroblastic tumor (IMT) is a locally invasive lesion that can mimic RMS in children and young adults. The diagnosis can be made endoscopically; however, in my experience, open biopsy is commonly needed to exclude RMS. The tumor consists of spindle cells with myofibroblastic differentiation in a collagen stroma with an inflammatory cell infiltrate. Abnormalities of the anaplastic lymphoma kinase gene *(ALK)* and the rain binding protein (RANBP2) have been reported. IMTs with these rearrangements are termed IMT-RAs and have a higher risk of local recurrence and metastasis (Li et al.. 2013). Tumors without rearrangement have been treated with celecoxib with or without surgery with some success (Berger et al., 2007; Chavez and Hoffman, 2013; Li et al., 2013).

Bladder hemangiomas or venous malformations of the bladder in children typically are accompanied by gross hematuria and can be difficult to distinguish from malignant lesions. An association between bladder hemangiomas and proteus syndrome (a rare hamartomatous disorder) has been documented in two patients (Lopez-Gutierrez and Jaureguizar, 2010). These lesions can be treated by partial cystectomy or laser ablation (Ashley and Figueroa, 2010; March Villalba, 2012; Takemoto et al., 2011).

Nephrogenic adenoma (NA) is a benign papillary lesion of the bladder that is associated with recurrent infections, radiation, bladder surgery, including bladder augmentation and other forms of bladder injury. It has been rarely reported in children with congenital anomalies involving the bladder (Broecker et al., 2011). NA has also been associated with renal transplantation (Mazal et al., 2002). Histologically, tumors have a polyploid or papillary pattern consisting of layers of cuboidal cells, which frequently organize themselves into tubular patterns (Heidenreich et al., 1999). Patients may have symptoms such as hematuria, dysuria, frequency, recurrent UTI, and bladder instability. Cystoscopy and biopsy are required for diagnosis. Treatment consists of minimizing or eliminating inflammatory stimuli (antibiotic prophylaxis or improvement in voiding function). Transurethral resection or fulguration has been used effectively. Recurrence is common, so long-term follow-up is warranted.

Malignant transformation is rare (Hartmann et al., 2006).

Female Genital Tract

Tumors of the Vulva and Clitoris

True vulvar tumors, as opposed to lesions originating from the vagina, are exceedingly rare. Primary sarcoma of the vulva represents only 1% to 3% of all vulvar malignancies. The most common pathology appears to be leiomyosarcoma, with RMS seen less frequently. Rhabdomyosarcoma of the vulva is therefore uncommon: the total number of patients enrolled in IRS-I to IRS-IV with vulvar sarcoma was 20. The age distribution was 12 patients younger than age 10 and 7 patients between the ages 10 and 20. Compared with patients with cancer of other female genital sites, a larger percentage of these patients have alveolar/undifferentiated histology, 9 of 20 (45%). However, because these tumors are typically localized at presentation, the prevailing theory is that patients have a favorable prognosis (Andrassy et al., 1995; Martelli et al., 1999). The usual presenting symptom is a labial/vulvar mass. Clinicians should be aware that tumors may also be seen as a clitoral or preclitoral mass (Bond et al., 1994; Ghushe and Drugas, 2007). Treatment may include upfront excision or biopsy followed by chemotherapy and local therapy per COG protocols; brachytherapy for treatment of vulvar lesions is also reported (Magne and Haie-Meder, 2007; Magne et al., 2008).

In a recent review from 1996 to 2016 at The Royal Children's Hospital of Melbourne, 17 cases of female GU RMS were identified, of which 2 presented with a vulvar mass and 1 with vulvar inflammation. In the group with perineal/vulvar mass, the ages of these patients were younger than 3 years of age or, in 1 case, age 13, demonstrating a typical bimodal distribution. The most common secondary symptom was inguinal adenopathy. The current COG protocol ARST1431 acknowledges that primary resection is often not feasible for vulvar lesions without significant disfigurement. In these cases, biopsy with primary chemotherapy should be performed because tumor response to chemotherapy can be significant.

In a review of 38 girls with nonmetastatic GU RMS treated with multimodal therapy, 4 presented with vulvar lesions, 2 had alveolar histology, and 2 were embryonal. Both patients with alveolar histology expired after relapse. In general IRS and European studies have reported favorable outcomes for patients with vulvar or vaginal lesions (Flamant et al., 1979; Heij et al., 1993; Raney et al., 1990). Primary yolk sac tumors (YSTs, endodermal sinus tumors) of the vulva have been reported in women and children as young as 22 months of age, although typically they are seen in the second to third decade of life. They are very rare and appear to be more aggressive than YSTs arising from the ovary or vagina. Serum alpha-fetoprotein (AFP) is a useful biomarker for monitoring therapy and recurrence. Excision or biopsy with regional node dissection followed by chemo/radiotherapy has been recommended. Recurrence and metastasis are common (Mochizuki et al., 2012).

Vaginal Rhabdomyosarcoma

The vagina is the most common location for RMS of the female genital tract. An analysis of IRS-I through IRS-IV identified 151 patients suffering from female genital tract RMS (vulva, vagina, cervix, uterine), of which 84 (54%) originated from the vagina. Most, 86%, were clinical group III, and 95% had botryoid/embryonal histology. Presenting complaints included vaginal bleeding, discharge, or a protruding mass (see Fig. 54.3; Andrassy et al., 1995, 1999). The management of vaginal RMS has changed dramatically since IRS-I. Each subsequent iteration of protocols has demonstrated a decreased need for surgical resection (IRS-I, 100%; IRS-II, 70%; IRS-III, 30%; IRS-IV, 13%) and excellent disease-free survival (Andrassy et al., 1995, 1999; Arndt et al., 2001). Overall survival in IRS-III was approximately 83% (20/24). Most patients today undergo upfront biopsy followed by chemotherapy with or without local control measures (Andrassy et al., 1995, 1999; Arndt et al., 2001). Between 1997 and 2008, COG conducted two consecutive low-risk RMS studies (D9602: 1997–2004 and ARST0331: 2004–2008); initially these studies limited or omitted radiotherapy for vaginal tumors and at times used lower doses of cyclophosphamide. Higher-than-expected local failure rates prompted COG investigators to recommend that radiation therapy (RT) should not be omitted. Despite these local failures OS was excellent in this series (Walterhouse et al., 2011). European studies have advocated brachytherapy, documenting excellent results with survival rates of 91% (Magne and Haie-Meder, 2007; Magne et al., 2008). In a recent study published by the 4 cooperative groups (US and European), patients with vaginal/uterine RMS had an OS at 10 years of 92%. More than one-half of the patients were cured without RT or radical surgery. About 70% of patients with vaginal RMS achieved local control with primary therapy. COG study ARST0331 recently reported an increased failure rate if the cyclophosphamide dose was diminished and radiation was omitted in certain low-risk group patients (group III vaginal/uterine RMS); for these patients 3-year EFS dropped to 57%, suggesting undertreatment for these patients. This cooperative group report also concluded that brachytherapy (BT) was preferable to external beam RT because of increased dose potential to the tumor site while diminishing off-target exposure. Using this approach, they were able to salvage patients with vaginal RMS who previously needed radical therapy (Minard-Colin et al., 2018).

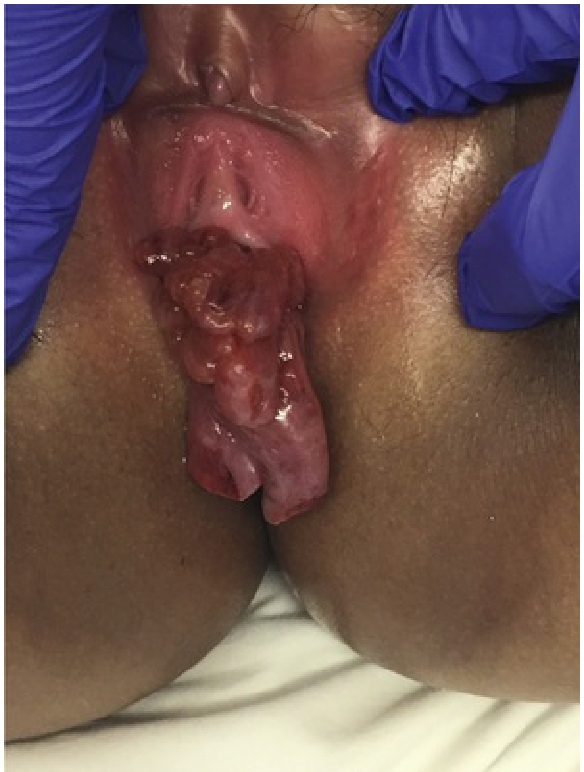

FIG. 54.3 Botryoid vaginal rhabdomyosarcoma emanating from the introitus of a young girl.

Cervical or Uterine Rhabdomyosarcoma

Cervical or uterine RMS is the second most common site of female genital RMS. A recent review using the SEER database described 26 cases from 1973 to 2006 (Kirsch et al., 2014). Of 151 patients with female GU sarcoma in IRS-I through IRS-IV, 49 had tumors of the cervix or uterine body (Arndt et al., 2001). Patients typically experience vaginal bleeding or an abdominal mass (the latter more common with uterine body tumors.) As with vaginal RMS, radical surgery has given way to organ-sparing approaches. Corpron et al. (1995) published the IRS-III and IRS-IV pilot experience, which included 14 patients ages 4 months to 17 years, the mean age of this group was 5.5 years old. Thirteen patients had embryonal pathology, 1 had an alveolar tumor. Of 8 patients with group III disease, 5 expired, but 4 of these succumbed because of sepsis and chemotherapy-related complications. All patients with group I disease, and even those with metastatic disease at presentation, survived (Corpron et al., 1995). A SIOP report using organ-sparing therapy reported survival of 10 of 11 patients with cervical/uterine RMS. The 2018 combined cooperative group report highlighted the differences between patients with cervical and uterine body RMS. The local control rate was 86% for patients with cervical lesions but only 70% for patients with uterine lesions. Lesion location has significant predictive value on the need for radical surgery. Patients with uterine lesions had approximately a 50% rate of requiring hysterectomy, whereas only 12% of cervical lesions required radical surgery. In addition, the cure rate for uterine relapses was lower than that of cervical relapse (Martelli et al., 1999). Organ-sparing procedures, such as trachelectomy, have been applied to select patients with cervical RMS (Kayton et al., 2009).

Ovarian Lesions

Pediatric urologists frequently become aware of patients with ovarian or adnexal masses, which occur as an incidental finding on imaging or during the workup of a symptomatic complaint, which is in fact related to an ovarian lesion. For these reasons, pediatric urologists should be familiar with these lesions.

Cystic Lesions

It is estimated that up to 98% of female newborns have small cysts visible on US. Cysts that would be clinically significant in newborns are uncommon, estimated at 1 in 2500 births. Of children up to age 8, 2% to 3% demonstrate an incidental cystic lesion (Brandt and Helmrath, 2005). Cysts present in the newborn period are usually related to maternal hormone levels, which drop after birth. Levels may rise again driven by the immaturity of the hypothalamic-pituitary-ovarian axis, which resolves around 2 to 3 years of life when patients settle into typical prepubertal hormone levels. A significant percentage of cystic lesions in newborns therefore involute spontaneously. When appropriate, evaluation of these lesions involves complete blood count (CBC), human chorionic gonadotropin (HCG), alfa-feto protein (AFP), lactate dehydrogenase (LDH), cancer antigen-125 (CA 125), US, and MRI (Templeman and Fallat, 2005). Intervention is typically indicated when lesions are indeterminate or symptomatic. Lesions that are benign, for example, simple cysts, are managed with organ-sparing approaches. Malignant cystic lesions in infants are rare, and even complex cysts in this age group are often observed (Brandt and Helmrath, 2005). Similarly, in prepubertal children up to 89% of cystic lesions are benign. These lesions should be observed only if (1) the cyst is clearly of ovarian origin, (2) the cyst is not complex, (3) AFP and HCG are normal, and (4) the patient is asymptomatic. Indications for surgery in prepubertal girls include persistence of the cyst, concern for malignancy, or any symptom, including changes induced by hormonally active cysts. **In adolescents ovarian cysts are usually the result of dysfunctional ovulation; treatment focuses on ovarian preservation.** Hormonal manipulation is frequently used; surgery is reserved for cysts that fail to resolve, persistent symptoms, or concern for malignancy.

Ovarian Malignancies

Ovarian tumors represent about 1% of childhood cancers. These tumors, similar to gonadal tumors in boys, are classified histologically as germ cell tumors, sex cord stromal tumors, or epithelial in origin. Tumors of epithelial origin are very rare before puberty (You et al., 2005). Germ cell tumors in girls arise from the primordial germ cells of the ovary and include teratoma (mature and immature), gonadoblastomas, and yolk sac (endodermal sinus) tumors. As in boys, gonadoblastomas occur in the setting of dysgenetic gonads and rarely metastasize. Sex cord stromal tumors in girls include theco-fibromas, Sertoli cell tumors, Leydig cell tumors, and granulosa cell tumors (GCTs). These tumors are hormonally active and may occur with precocious puberty. Their course is typically benign (Schultz et al., 2006).

The incidence of an ovarian mass in prepubertal girls is approximately 2.6 in 100,000; of these 50% are malignant and the other half are benign. Of the malignant tumors, the large majority (85%) are germ cell tumors, 8% are epithelial malignancies, and 5% are sex cord tumors.

Germ Cell Tumors

GCTs of the ovary exhibit a bimodal age incidence with a group at less than

1 year of age and another group between the ages of 15 and 19. Presentation varies and can include abdominal pain, distention, or a mass. Other symptoms include acute abdomen, ovarian torsion, and precocious puberty. GCTs are of varied histologic origin. They may be divided into 2 broad groups: seminomas (dysgerminomas) and nonseminomas (YST, teratomas, embryonal carcinomas, and choriocarcinomas). Teratoma is the most common subtype, and they can be benign or malignant. Mature teratomas (dermoid cysts) are typically benign and treated by resection. Immature teratomas and yolk sac tumors can exhibit aggressive behavior and are staged and treated along COG protocols. Dysgerminomas are most commonly found in adolescents and are composed of undifferentiated germ cells. YSTs comprise all 3 germ cell layers and can be aggressive. Tumor markers (AFP, B-HCG, and LDH) can be useful diagnostically; YSTs along with rare embryonal carcinomas and choriocarcinomas produce serum markers, which play a role in treatment and follow-up. Prognosis for these tumors is generally very good. COG protocol 9048 treated these tumors with resection and platinum-based multiagent chemotherapy and demonstrated an overall 6-year survival of 95% and 93% for stage I and stage II tumors, respectively (Rogers et al., 2004). Reports of excellent outcomes for children with stage III disease are also available. More recently observation alone for patients with stage I tumors has been studied. Although EFS decreased, the overwhelming majority of patients were effectively treated by chemotherapy upon recurrence (Billmire et al., 2014). Fertility preservation approaches are pursued when appropriate.

Sex Cord Tumors

Juvenile granulosa cell tumors (JGCTs) and Sertoli-Leydig tumors are exceedingly rare ovarian malignancies. JGCTs often occur with precocious puberty because of estrogen production. Early stage lesions can be treated with surgery alone, whereas more advanced stages require chemotherapy. Sertoli-Leydig cell tumors frequently produce androgens, so they may be seen with virilization, abdominal pain, or a mass. Again low-stage lesions may be treated with surgery alone, whereas higher stages may require multimodal therapy. In general, prognosis for these lesions is favorable (Schultz et al., 2005, 2006).

Epithelial Tumors

Cystadenomas can be benign or malignant and are most commonly seen in older patients but have been reported in children. Small cell carcinoma in children is extremely rare but has also been reported in the pediatric population (Schultz et al., 2005, 2006).

Key Points

- Vaginal RMS is the most common female genital site.
- The majority of embryonal histology and organ preservation strategies have resulted in excellent OS.
- Ovarian tumors make up 1% of all childhood cancers. Ovarian tumors are histologically classified as germ cell, sex cord, or epithelial tumors.

Testicular Tumors

Prepubertal testicular tumors differ markedly from those of postpubertal males in that benign lesions are more common and malignant tumors have a more favorable course. Estimates suggest that testicular tumors account for roughly 1% of pediatric solid tumors, with an incidence of 0.5 to 2 per 100,000 children. Much of our information regarding these tumors comes from the Pediatric Testis Tumor Registry (PTTR), established by the Urology Section of the American Academy of Pediatrics, or from large single- or multi-institutional series. Conflicting data regarding the most frequent pathologic variant have raised questions about enrollment bias in the PTTR. Fortunately, these discrepancies do not affect clinical management, allowing for clear and simple algorithms.

Epidemiology

The PTTR suggests that the most common pathological diagnosis in children with a testicular mass is a YST, followed by teratoma (Ross et al., 2002). Similarly, a recent study from the National Cancer Database reported YSTs as the most common pathology; however, this registry does not record benign lesions such as teratoma (Maizlin, 2018). A large single-center series from Turkey also found that YSTs were most common (Ciftci et al., 2001), but these findings are reversed in most single- or multi-institutional series (Agarwal and Palmer, 2006; Metcalfe et al., 2003; Shukla et al., 2004). A review on the subject from 4 large pediatric hospitals that included 98 patients younger than age 12 found that teratoma was present in 48% of children, YST in 15%, epidermoid cyst in 14%, JGCT in 5%, Leydig cell in 4%, Sertoli cell in 3%, and mixed gonadal stromal in 1%. The remaining 9% included diagnoses such as gonadoblastoma, lymphoma, cystic dysplasia, and IMT (Pohl et al., 2004). Based on this analysis more than 74% of prepubertal testis tumors are benign in nature. **This topic was reviewed in detail by Agawarl and Palmer, who acknowledge the discrepancy and conclude simply that teratoma and YST are the most common cause of a testicular mass** (Agarwal and Palmer, 2006). Tumor incidence peaks near age 2, and a second rise in incidence is seen in the peripubertal period (Haas and Schmidt, 1995; Haas et al., 1995; Li and Fraumeni 1972). Karmazyn et al. (2018) recently looked specifically at children ages 5 to

12 years with testicular lesions and found that none of the lesions were malignant. This report is limited by the fact it is retrospective and a single-institution experience. Tumors are more frequent in whites than in non-whites (Walsh et al., 2008). Incidence appears to vary with geographic location. When considering all males, (pre- and postpubertal) some suggest that the incidence of testicular GCTs has been rising; however, it appears that postpubertal, not prepubertal, tumors account for this increase (Reuter, 2005).

Pathogenesis and Molecular Biology

GCTs comprise a heterogeneous group of neoplasms that derive primarily from the gonads but may arise from extragonadal sites along the migration route of the primordial germ cells to the genital ridge (midline mediastinum, peritoneum, and sacrum) (Looijenga and Oosterhuis, 1999; Oosterhuis and Looijenga, 2003; Slowikowska-Hilczer et al., 2003). As a group, testicular GCTs make up 98% of malignant testicular tumors and are the most common cancer in men ages 15 to 35 (Bosl and Motzer, 1997). High levels of maternal estrogens, low and high birth weights, neonatal jaundice, and disorders of sexual development (DSD) have been associated with the development of GCT. Many of these factors support the concept that initiating events occur in the pre- or perinatal period (Depue et al., 1983; Ekbom and Akre, 1998; Reuter, 2005; Richiardi et al., 2002).

The most widely accepted association with GCT is cryptorchidism, with 10% of cases linked to a history of undescended testis (Halme, Kellokumpu-Lehtinen et al. 1989a,b; Schottenfeld et al., 1980). Patients with cryptorchidism have a fourfold higher lifetime risk of developing GCT. It does not appear that this risk completely returns to baseline after surgical correction (Giwercman et al., 1987; Halme et al., 1989a,b; Schottenfeld et al., 1980). Finally, as is discussed in subsequent sections, patients with DSD are known to be at risk for the development of GCT (Collins et al., 1993; Rutgers and Scully, 1987, 1991; Skakkebaek et al., 2003). Patients with hypovirilization and gonadal dysgenesis are at highest risk.

Much remains unknown regarding the molecular pathogenesis of GCT. Intratubular germ cell neoplasia (IGCN) is considered by many to be a precursor lesion to GCT. Two theories predominate regarding the development of IGCN. The first suggests that aberrant chromatid exchange events lead to a chromosome 12p copy number increase. This in turn allows zygote-pachytene spermatocytes to avoid the apoptotic effects of p53 and become cancerous (Chaganti and Houldsworth, 1998, 2000). The second theory maintains that fetal gonocytes undergo abnormal cell division because of environmental factors and give rise to IGCN. Polyploidization thus precedes chromosome 12p abnormalities. These cells become vulnerable to postnatal or postpubertal development of invasive cancer (Chaganti and Houldsworth, 1998; Looijenga et al.; 1999; Skotheim and Lothe, 2003). Pediatric cases are mostly diploid, with the exception of YSTs, which may be nondiploid. GCTs in children have been characterized by deletions of 1p, loss of chromosome 6q, and abnormalities of chromosome 2 and 3p (Jenderny et al., 1996; Schneider et al., 2001; Silver et al. 1994).

The COG conducted the largest study evaluating family history of cancer and subsequent development of malignant GCT (Poynter et al., 2010). The study enrolled 278 cases and 423 controls. No association was observed between a family history of cancer and GCT in the group as a whole. The study did observe an increased risk of GCT in males, when a relative was diagnosed with cancer before the age of 40 years (OR = 2.56, 95% CI 1.02–6.44). Recently, Poynter et al. (2012) evaluated several susceptibility loci that had been identified in adult GCTs in a cohort of pediatric GCTs. Fifty-two cases from patients age birth to 21 were evaluated. The majority of patients were female and the tumors were predominantly teratomas and yolk sac tumors. The SNP for *SPRY4* was significantly associated with an increased risk of GCT in boys and in adolescent males. *BAKI* was associated with gonadal tumors in both sexes. Prior studies had identified similarities in chromosomal abnormalities present in adolescent males and adult males with GCTs. These included losses on chromosomes 11, 13, and 18 and gains on 7, 8, and X (Bussey et al., 1999).

Presentation, Evaluation, and Staging

Testicular tumors most commonly occur as a painless mass. Alternatively, the lesion may be incidentally discovered by US of the scrotum to rule out torsion or investigate scrotal pain. A hydrocele is present in 15% to 20% of cases. The differential includes other intrascrotal processes such as paratesticular tumors, epididymitis, benign epididymal lesions, hernias, and hydroceles. Patients with hormonally active tumors may be referred for precocious puberty. Patients with undescended testis may present when a testicular mass predisposes to intrabdominal torsion (Agarwal and Palmer, 2006).

Ultrasonography

Although the sensitivity of US approaches 100% for detection, it is important to recognize that US cannot reliably distinguish benign from malignant testicular lesions. Common sonographic features of benign and malignant testicular masses are summarized in Fig. 54.4 and discussed later.

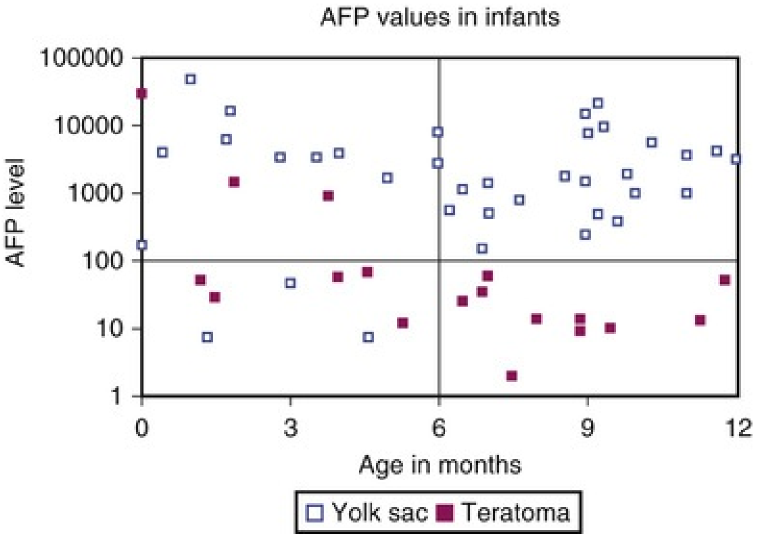

FIG. 54.4 α-Fetoprotein (AFP) levels in infants with yolk sac tumor and teratoma (ng/mL). (From Ross JH: Prepubertal testicular tumors. *Urology* 74:94–99, 2009.)

Teratomas appear as heterogenous complex lesions on US, reflective of their composition, which typically includes three germ cell layers. They may contain cystic and solid components. Bony elements appear as calcifications with shadowing. Adipose tissue appears as echogenic areas without shadowing. Epidermoid cysts represent a monolayer teratoma and have a characteristic appearance described as "onion skin," made up of concentric rings of alternating hypo-/hyperechoic lesions. YSTs are typically well circumscribed and heterogenous in appearance. These tumors may be hypervascular in appearance and may have areas of hemorrhage and necrosis. Sertoli and Leydig cell tumors are similar in appearance and commonly occur as a well-circumscribed hypoechoic mass. GCTs may contain cystic and solid components. Gonadoblastomas are solid, hypoechoic lesions and unlike other testicular lesions, may occur bilaterally.

Interpretation of Biomarkers in Children

Serum biomarkers play an important role in the diagnosis and management of pediatric testicular lesions. Human chorionic gonadotropin-B (b-HCG) is rarely elevated in prepubertal tumors. AFP is normally produced by the fetal yolk sac, liver, and gastrointestinal tract. **Serum AFP is elevated in YST; measurement of AFP levels is valuable for diagnosis, staging, and management of patients with YST. As a result of the physiologically persistent elevation in children younger than 1 year of age, interpretation of AFP levels in young children undergoing evaluation for testis mass must be performed with caution.** Although the accepted half-life of AFP is 5 days, levels may be particularly high after birth, and a normal T1/2 may not occur for up to 4 months. AFP levels frequently do not come down to basal levels until 6 to 8 months of age, and in some patients elevated levels may persist until 12 months. Several features of AFP level analysis bear mention. In YST, AFP is elevated (>10 ng/mL) in 92% of cases. **If a child older than 1 year of age has a testicular mass and an elevated AFP, it is likely the patient harbors a YST, and an organ-sparing procedure should not be entertained. Conversely, a normal AFP provides considerable assurance that the mass under evaluation is benign** (Ross et al., 2002). Ross et al. have made other nuanced observations that may help clinicians:

1. In children younger than age 1 with YST, the median AFP levels are higher than children with teratoma.
2. In children older than 6 months with teratoma, AFP levels rarely exceed 100 ng/mL (see Fig. 54.4).

Staging

Careful physical examination is indicated, with particular focus on any evidence of precocious puberty, suggesting a hormonally active tumor. Disseminated disease is rare in children. After ultrasonography and serum tumors marker analysis, if concern exists that a lesion is malignant (elevated AFP), CT of the abdomen and retroperitoneum should be performed. The most common site of metastatic disease is the lung, which may be assessed by CT or radiograph. The COG staging system is a postsurgical system based on assessment after primary orchiectomy and imaging (see Table 54.5).

TABLE 54.5

Children's Oncology Group Staging System for Testicular Germ Cell

Tumors

STAGE	EXTENT OF DISEASE
I	Tumor is limited to testis, completely resected by high inguinal orchiectomy. No clinical, radiographic, or histologic evidence of disease beyond the testes. If scrotal orchiectomy has been performed, all margins are negative after resection of proximal cord structures to the level of the internal inguinal ring. Tumor markers are negative after appropriate half-life decline. Patients with normal or unknown tumor markers at diagnosis must have a negative ipsilateral retroperitoneal node sampling to confirm stage I disease, if radiographic studies demonstrate lymph nodes >2 cm.
II	Microscopic residual disease is present in the scrotum or high in spermatic cord (<5 cm from proximal end). Tumor markers remain elevated after appropriate half-life interval. Tumor rupture or scrotal biopsy before complete orchiectomy.
III	Retroperitoneal lymph node involvement. Lymph nodes >4 cm by CT are considered metastases. Biopsy needed to document nodal metastases in lymph nodes >2 cm and <4 cm.
IV	Distant metastatic deposits

CT, Computed tomography.

Tumors Associated With Disorders of Sexual Development

Patients with DSD and dysgenetic testis or hypovirilization have an increased incidence of testicular tumors. Patients harboring Y chromosomal material in their karyotype are at highest risk. The noninvasive precursors of GCTs (primarily seminoma/nonseminoma and dysgerminoma/nondysgerminoma) in these patients are presumed to be carcinoma in situ and gonadoblastoma (CIS and GB, respectively) (Cools et al., 2006; Skakkebaek, 1972). Both arise from fetal germ cells. Immunohistochemical, mRNA analysis, and the resemblance of subsequent tumors suggest a common origin for carcinoma-in-situ (CIS) and gonadoblastoma (GB) (Gillis et al., 2007; Looijenga et al., 2007; Pleskacova et al., 2010). The pathogenesis of tumors in patients with DSD involves the transformation of immature germ cells. Several key factors in this transformation have been identified. OCT3/4, a transcription factor that has antiapoptotic functions in primordial germ cells (PGC) and can be used to identify early fetal germ cells, is one such factor (Cheng et al., 2007). Another crucial element appears to be the expression of testis-specific protein Y-encoded (TSPY) in the germ cells of DSD gonads (Oram et al., 2006). TSPY is the most likely candidate for the gonadoblastoma locus on the Y chromosome (GBY) and defines the section of the Y chromosome that appears to confer risk for the development of GCT (Lau et al., 2009). It has been proposed that double staining for OCT3/4 and TSPY can help identify dysplastic cells early in DSD patients (Kersemaekers et al., 2005). In addition, recent studies have identified that stem cell factor (SCF) is also a potentially useful CIS/GB marker (Stoop et al., 2008). Combined analysis on biopsy specimens could help identify those at risk (Pleskacova et al., 2010). A consensus statement on the risk associated with various DSD diagnoses and recommended management was released in 2007 and provides guidance for the counseling and management of these patients (see Table 54.6; Looijenga et al., 2007; Pleskacova et al., 2010).

Germ Cell Tumors

Teratomas are, according to some series, the most common testicular tumor in children and consist of variable combinations of the 3 primitive embryologic germ cell layers (Metcalfe et al., 2003; Pohl et al., 2004; Shukla et al., 2004). They pose a characteristic ultrasound appearance (described earlier) and do not express AFP. Unlike adult males, the majority of prepubertal lesions are benign, consisting of mature elements only (Gobel et al., 1998). Rare reports of teratomas harboring immature elements and metastasizing are present in the literature (De Backer et al., 2008; Gobel et al., 1998, 2006). The combination of AFP measurements and characteristic US appearance can suggest to the surgeon the presence of teratoma. **The preferred treatment for suspected teratomas is partial orchiectomy (see description of technique later)** (Makari et al., 2010; Ross, 2009; Ross and Kay, 2004, Shukla et al., 2004).

Epidermoid cysts are benign lesions in prepubertal males and may account for more than 15% of prepubertal testis lesions (Pohl et al., 2004). They consist of cysts lined with keratin-producing epithelium. They demonstrate a mixed appearance (hypo- and hyperechoic) on ultrasound and AFP levels are normal. They are managed by testis-sparing surgery. No surveillance is required after treatment (Ahmed et al., 2010; Walsh and Rushton, 2000).

YST has been variably reported to be the first or second most common testicular tumor in prepubescent males. It is the most common malignant prepubertal tumor. YSTs have also been referred to as endodermal sinus tumor or juvenile embryonal carcinoma. They are typically well-demarcated, heterogenous masses, which may have hemorrhage or necrosis on US. On gross appearance they are solid and gray-yellow in color. YSTs express positive stain for periodic acid–Schiff and AFP. **Schiller-Duval bodies consist of a central blood vessel surrounded by two layers of tumor cells and are pathopneumonic for YST (see Fig. 54.5). AFP levels are elevated in about 90% of patients and represent a reliable marker for follow-up studies.** The majority of prepubertal cases (>85%) are stage I at diagnosis (Grady, 2000; Grady et al., 1995). When metastases occur, YST often exhibit hematogenous spread to the lungs (~20%), without retroperitoneal disease. For these reasons **retroperitoneal lymph node dissection (RPLND) plays very little role in prepubertal YST. RPLND is used exclusively for patients with a residual retroperitoneal mass or persistently elevated AFP after chemotherapy and orchiectomy** (Ahmed et al., 2010). About 20% of stage I tumors recur after orchiectomy alone. Post-orchiectomy stage I patients undergo a rigorous surveillance protocol, which includes chest and retroperitoneal imaging and tumor marker assessment (Connolly and Gearhart, 1993). An inguinal incision should be used in all patients with a testicular mass. When a patient with a YST has undergone a trans-scrotal orchiectomy, if the pathological margins are negative, the patient may be treated as stage I, so long as the cord is resected to the inguinal ring. If a prior transscrotal biopsy has been performed, the patient should undergo complete orchiectomy and is considered stage II (Rogers et al., 2004). Hemiscrotectomy is not required in these cases. If enlarged nodes are present on imaging, biopsy is indicated. Patients with adenopathy and elevated AFP are treated as stage III. **Treatment protocols that use multiagent chemotherapy are recommended by the North American, English, and European groups. Survival, even for patients with metastasis, approaches 100%** (Haas et al., 1999; Lo Curto et al., 2003; Mann et al., 1989, 2000; Schlatter et al., 2003).

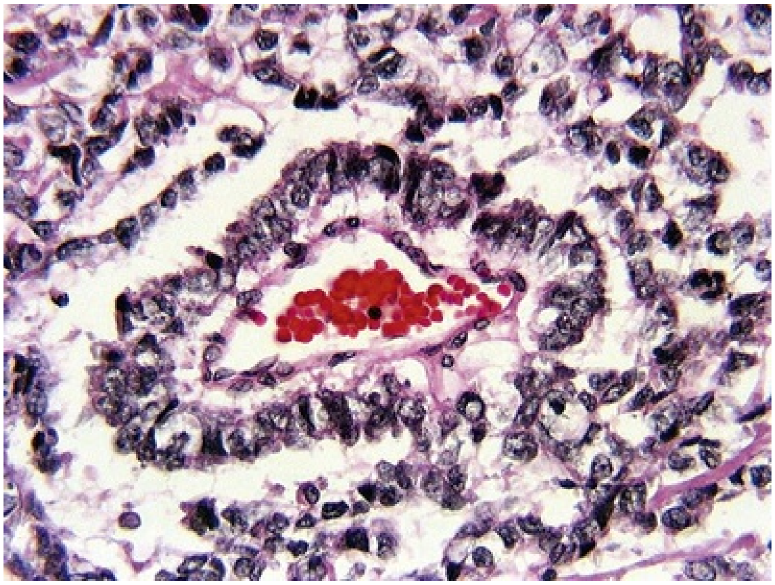

FIG. 54.5 Schiller-Duval body. (From Department of Pathology, University of Pittsburgh, http://path.upmc.edu/cases/index.html.)

Gonadal Stromal Tumors

JGCTs are described to be the most common testicular tumors affecting neonates. They are easily differentiated from YSTs, because they stain negatively for AFP and stain positively for markers such as inhibin alpha. They have been reported in patients with ambiguous genitalia (Cortez and Kaplan, 1993; Shukla et al., 2004). These lesions are benign and are treated with a testis-sparing approach.

Leydig cell tumors (LCTs) are hormonally active and are associated with precocious puberty. LCTs are responsible for about 10% of all cases of precocious puberty. Other causes of precocious puberty include pituitary lesions, Leydig cell hyperplasia, large-cell Sertoli cell tumors, and hyperplastic nodules in congenital adrenal hyperplasia (CAH) patients. If the practitioner is confused, they can exclude pituitary lesions by demonstrating an increased testosterone level with age-appropriate LH and FSH. Leydig cell hyperplasia patients have normal urinary 17-ketosteroids. Boys commonly are seen between the ages of 5 and 10 years with virilization, although a small percentage appear with gynecomastia (Cortez and Kaplan, 1993). **The tumors may be small and appear as yellow-brown nodules; histologically they contain diffuse layers of polygonal cells and about 40% demonstrate Reinke crystals. Reinke crystals contain lipofuscin pigment and are rod-shaped, crystal-like structures 3 to 20 µm in diameter** (see Fig. 54.6). Their purpose is unknown but they are unique to Leydig cell tumors. Elevated testosterone levels are commonly found, and these may drop after resection, but the virilizing features may persist. Because of the small size of the lesions intraoperative localization may be difficult. The lesions are managed with an organ-sparing approach; recurrence is very uncommon (Wegner et al., 1997).

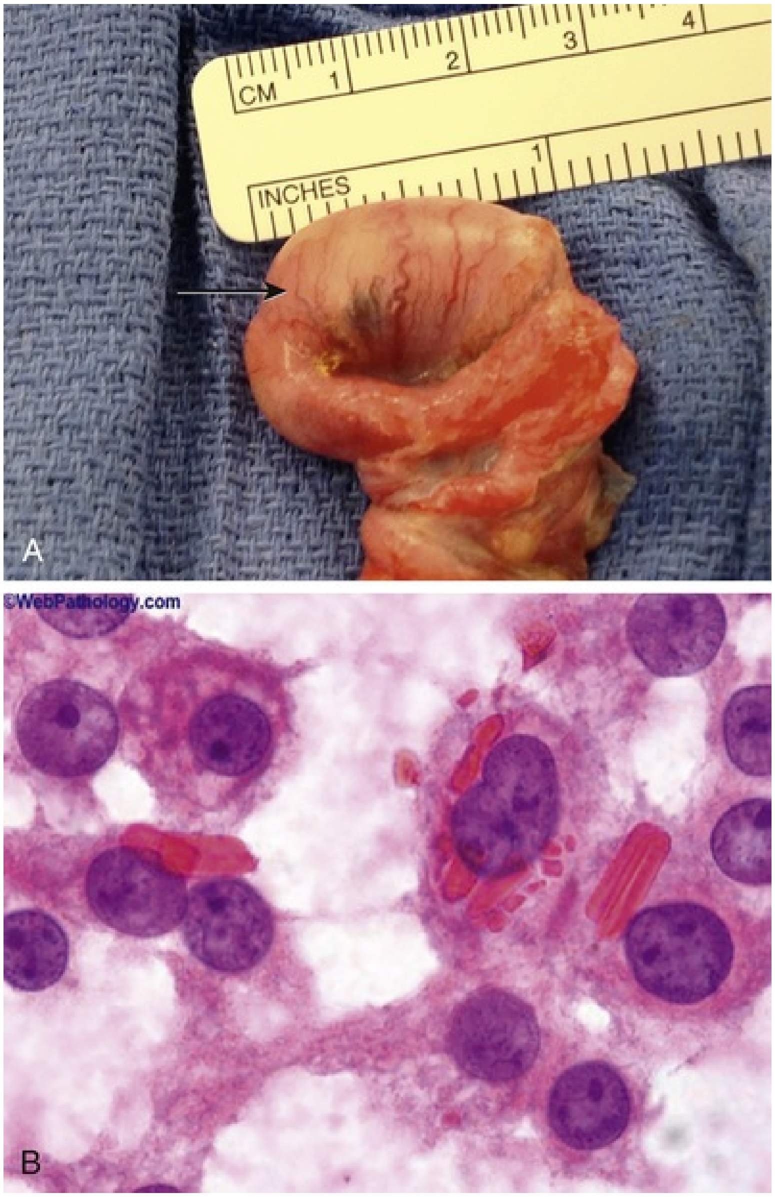

FIG. 54.6 (A) Leydig cell tumor demonstrating characteristic brown appearance related to abundant lipofuscin pigmentation. (B) Reinke crystals. (*A,* Courtesy Fernando Ferrer, MD; *B,* from http://www.webpathology.com.)

Sertoli cell tumors typically occur at an earlier age than Leydig tumors (mean age 52 months) and have been reported in children from age 4 months to age 10 (Thomas et al., 2001). The usual presentation is a painless mass. They have been associated with endocrinologic and genetic syndromes such as Peutz-Jeghers and Carney syndromes. Ten percent of these tumors are hormonally active, and patients may have virilization or feminization (Gabrilove et al., 1980; Thomas et al., 2001). The tumors are usually firm, well-circumscribed, and tan-gray in gross appearance. They may contain areas of hemorrhage or cysts. For infants and children up to age 5, orchiectomy is usually sufficient treatment unless the tumor demonstrates the following features: large size (>5 cm), vascular invasion, necrosis, cellular atypia, or increased mitotic activity. Tumors with these features or those occurring in children older than age 5 merit a full staging evaluation. Children with retroperitoneal metastasis may be candidates for RPLND, chemotherapy, and radiation. Large-cell calcifying Sertoli cell tumors are a distinct entity seen in prepubertal children and adolescents; they can be managed by simple orchiectomy.

Leukemia and Lymphoma

The most common cancers metastatic to the testis are leukemia and lymphoma. Up to 20% of patients with bulky disease may have gonadal disease or relapse in the testis (Askin et al., 1981). Because of the high success rates of systemic chemotherapy and whole-body irradiation, routine testis biopsy is no longer required in these patients (Trigg et al., 2000). Burkitt lymphoma may occasionally occur as a testicular lesion, and follicular lymphomas may occur primarily in the testis (Finn et al., 1999; Lamm and Kaplan, 1974).

Testicular Microlithiasis

The incidence of testicular microlithiasis in asymptomatic males age 0 to 19 has been reported to be 2.4% (Goede et al., 2009). A concern that these lesions are harbingers of testicular cancer has prompted some to recommend surveillance with US (Furness et al., 1998; Leenen and Riebel, 2002). However, more recent studies have determined that screening US is not required for patients without risk factors such as infertility associated with atrophic testis and microlithiasis or testis cancer and contralateral microlithiasis (Hoei-Hansen et al., 2005; Holm et al., 2003). Controversy on this subject continues: some publications have called into question if an association between microlithiasis and GCT exists at all in children, whereas others continue to cite a strong association between microlithiasis and primary testicular tumors (Trout et al., 2017; Volokhina et al., 2014). Routine self-examination is the current recommendation followed by many.

Management Algorithms

With the recognition that the majority of these tumors are benign, management of prepubertal testis tumors has evolved from radical orchiectomy. This evolution began in the 1980s, facilitated by improvements in ultrasonography and the ability for frozen section analysis to accurately distinguish benign from malignant lesions. Today patients are preferentially treated with excisional biopsy, intraoperative frozen section analysis, followed by an organ-preserving procedure. The exception is when preoperative AFP or intraoperative biopsy suggests malignancy. Ross et al. (2002) published their recommended approach after reviewing the results from the prepubertal testis tumor registry of the urology section of the American Academy of Pediatrics (see Fig. 54.7). A recent review by Woo and Ross (2016) discusses the evolving thought on partial orchiectomy in adolescent males. European guidelines have allowed for consideration of partial orchiectomy for synchronous and metachronous bilateral lesions an in the case of a solitary testis. This is an evolving area: these patients have been managed primarily according to adult protocols.

(From Ross JH, Rybicki L, Kay R: Clinical behavior and a contemporary management algorithm for prepubertal testis tumors: a summary of the Prepubertal Testis Tumor Registry. *J Urol* 168[4 Pt. 2]:1675–1678, 2002.)

Key Points

- A large percentage of prepubertal testis tumors are benign; therefore testicular preservation approaches are often indicated.
- Ultrasonography cannot reliably distinguish benign from malignant lesions.
- AFP is the relevant biomarker in prepubertal testis tumors, and elevation is associated with YSTs.

- AFP levels must be interpreted with caution because physiologic elevation above normal values is common in children younger than age 1.

Testis-Sparing Surgery Technique

Patients undergoing testis-sparing surgery should be counseled regarding the potential need for radical orchiectomy. Preoperative coordination of intraoperative frozen section is required. If the tumor is not palpable, intraoperative sonography should be available. The testicle is approached through an inguinal incision, and early vascular control of the spermatic cord is achieved with a vessel loop or Penrose drain. The gonad is delivered through the inguinal incision, and the tunica vaginalis is incised to expose the testicle. With lesions involving or immediately adjacent to the tunica albuginea, an elliptical incision beyond the tumor margins should be made in the tunica albuginea. In patients with nonpalpable lesions, I have used intraoperative sonography for localization. Ice may be applied to reduce warm ischemia time. While awaiting intraoperative frozen pathology, the surgeon may reapproximate tunica albuginea with 5-0 running interlocked polydioxanone suture. Intraoperative considerations for testis-sparing surgery include the presence of sufficient normal parenchyma to facilitate closure of the testis. If intraoperative frozen pathology reveals malignancy, a radical orchiectomy is completed. To my knowledge, no reports document a malignant diagnosis on final pathology when intraoperative frozen pathology revealed a benign diagnosis.

Paratesticular Rhabdomyosarcoma

Paratesticular RMS arises from the testicular tunics, epididymis, or the spermatic cord. Up to 40% of paratesticular lesions are due to RMS (Shapiro and Strother, 1992)**. The tumor may invade locally and/or involve the scrotal wall. These tumors represent 7% to 10% of all GU RMS. Peak incidence occurs between ages 1 and 5, a bimodal age distribution has been reported by some, with peaks at less than 1 year of age and at 16** (Ahmed et al., 2010). In general, patients with paratesticular RMS do better than those with tumors arising at other sites because (1) the overwhelming majority of these tumors are stage I at diagnosis (up to 80%), unlike RMS in general, in which only 13% of tumors are stage I; (2) more than 90% of patients have embryonal histology; and (3) those patients with more aggressive histology, alveolar, appear to do better than patients with alveolar histology at other locations (Anderson et al., 2004; Ferrari et al., 2002, 2004; Wiener et al., 1994, 2001). A recent report from Germany looked at paratesticular RMS patients enrolled in studies between 1990 and 2013; all patients' pathology and molecular characteristics were re-evaluated. Seven patients were analyzed at a median follow-up of 7 years; all patients were alive. Four patients demonstrated areas consistent with alveolar histology on pathological review; all 7 patients were fusion negative, further supporting a biologic difference, which likely explains the improved outcomes of these patients (Seitz et al., 2016a,b).

Presentation and Staging

Patients have a unilateral, firm, painless scrotal mass. The lesion may or may not be distinct from the gonad. Ultrasound, typically the first interrogation, reveals a hyperechoic, heterogenous, solid mass. Evaluation of these patients involves assessment of testicular tumors markers, liver function tests, and evaluation of the chest for metastasis using CT. Complete retroperitoneal imaging using double-contrast, thin-cut CT (<10 years old = 5 mm and >10 years old = 7 mm) up to the level of the ipsilateral hilum is essential, because this is the primary lymphatic landing site, and nodes are positive in up to 20% of patients.

Treatment

Patients with suspected paratesticular tumors should undergo inguinal exploration and radical orchiectomy with resection of the spermatic cord up to the internal ring inguinal and marking of the stump site. Biopsy should be avoided because it may lead to contamination of the operative field. In cases in which biopsy is considered essential, isolation of the gonad and the application of an atraumatic tourniquet is required. If frozen section biopsy is consistent with tumor, the cord should be transected above the tourniquet and the specimen kept in isolation. Any unprotected spill results in upstaging. For patients referred after trans-scrotal biopsy or resection, standard recommendations have included pretreatment re-excision of the surrounding scrotal skin. Recent data from the German and Italian cooperative group question the necessity for this (Dall'Igna et al., 2003; Stewart et al., 2003).

The appropriate management of regional lymph nodes is essential in patients with paratesticular rhabdomyosarcoma. **Patients younger than 10 years old who are considered to be in clinical group 1 (total gross resection with negative margins) who have a negative retroperitoneal CT scan do not require further surgical treatment** (Wiener et al., 2001). Patients younger than 10 years old who have evidence of positive nodes on CT scan should undergo staging ipsilateral (SI) RPLND; if all tumor is removed the patients are classified as clinical stage II. A nerve-sparing ipsilateral technique is recommended by COG protocols and, in the hands of experienced surgeons, a laparoscopic approach is acceptable (Cost et al., 2012; Tomaszewski et al., 2010). Patients who have grossly positive lymph nodes on staging CT scan can be managed simply by confirmatory biopsy and are considered to be stage III. **As opposed to children younger than age 10, children older than 10 should always undergo SIRPLND.** Paratesticular tumors rarely involve inguinal lymph nodes. However, when scrotal involvement occurs, inguinal node sampling should be performed. These are not considered “regional nodes,” and patients with positive nodes are classified as clinical group IV.

Role of Retroperitoneal Lymph Node Dissection

Original protocols, which frequently used non–nerve-sparing bilateral RPLND for patients with paratesticular RMS, resulted in significant morbidity, such as intestinal obstruction (10%), ejaculatory dysfunction (8%), and lower extremity edema (5%). The IRS-III analysis of 121 patients undergoing RPLND for paratesticular RMS compared CT evaluation of lymph nodes (LN) with the pathologic results of RPLND (mostly unilateral). Eighty-one percent of the 121 patients had CT-negative LN status; of these 14% had positive nodes on pathological examination. Patients with negative nodes had a much higher 5-year EFS, 96% versus 69% (Wiener et al., 1994). After IRS-III, strategy shifted and patients enrolled in IRS-IV did not undergo RPLND if they had negative nodes on imaging (Crist et al., 2001). Further comparison between the two studies demonstrated a stage shift in patients categorized as group I, such that 68% of IRS-III patients were group I versus 82% in IRS-IV. This change was reflective of the reliance of CT only for staging in IRS-IV. Comparative analysis between these studies demonstrated that adolescents (>10 years old) were much more likely to have retroperitoneal disease and fared worse than children younger than 10 (Wiener et al., 2001). As a result of these findings, COG recommendations shifted back so that all children older than 10 should undergo SIRPLND.

The Italian and German groups compared the accuracy of CT versus pathological assessment of the retroperitoneum and found that only 1 of 72 patients with a negative CT had positive retroperitoneal lymph nodes. SIOP studies MMT 84 and 89 treated patients with nonmetastatic, paratesticular RMS without RPLND (Stewart et al., 2003). A total of 96 patients were enrolled; 25 of these patients were 10 or older. Only 1 patient underwent lymphadenectomy as initial therapy. Five-year OS was 92% and EFS was 82%. Relapse occurred in 16 patients, 14 in the retroperitoneum. Eight were salvaged with second-line chemotherapy, radiation, and in some cases, lymphadenectomy. Although the authors recognize that these sixteen patients may have been understaged, they point out that OS is comparable with that of IRS (Stewart et al., 2003). Older age and primary tumors greater than 5 cm predisposed to poor outcome. A recent SEER-based study identified 225 cases of paratesticular RMS. Among 173 patients older than 10 years of age, LN dissection was found to improve the 5-year OS rate from 64% to 86% ($P < 0.01$). Conversely, patients aged younger than 10 years fared well regardless of LN dissection status; the 5-year OS rate was 100% and 97%, respectively (Dang et al., 2013). Seitz reported the cumulative results of CWS-86, -91, -96, and -2002P, which included a total of 147 patients. The 5-year OS was 95.5% and EFS was 89.8%. Contrary to COG protocols the authors recommend that initially positive LNs be re-imaged after 7 to 10 weeks; those with evidence of persistent LN enlargement (particularly those >10) should have RT or RPLND. They suggest that patients with adenopathy may be observed based on the finding that few patients actually had positive nodes after chemotherapy (Seitz et al., 2016a,b).

In summary, although some European collaborative groups have avoided RPLND, COG recommends RPLND for all children older than 10 hoping to avoid failure in the retroperitoneum and the burden of second-line therapy. Despite data supporting these recommendations, an analysis of the SEER database recently published showed that one-third of adolescents still do not undergo RPLND, despite a distinct survival advantage (OS at 5 years 92% vs. 64%) (Hamilton et al., 2018). Recently, the utility of PET-CT for detecting nodal involvement in RMS has been reported; it is possible that will be a useful adjunct for retroperitoneal staging (Burnette et al., 2013).

Outcomes

Before the advent of multimodal therapy, surgery alone provided for a 2-year EFS of 50% (Sutow et al., 1970). In most recently reported studies from the SIOP and MMT 84 and 89, the 5-year OS was 92% and the EFS at 5 years was 82% (Stewart et al., 2003). These studies identified age older than 10 and a primary tumor larger than 5 cm as adverse prognostic factors. The Italian and German cooperative groups jointly reported on 216 patients who had excellent 5-year OS and EFS of 94.6% and 90.7%, respectively (Ferrari et al., 2002). Patients with metastatic disease had a 5-year survival of only 22%. Like SIOP this group has also transitioned away from RPLND. Three-year overall survival in IRS-III was 96% and in IRS-IV was 92% (Crist et al., 1995, 2001).

A unique feature of paratesticular RMS is the good outcome of patients with alveolar histology now known to be related to fusion-negative status (Anderson et al., 2004; Ferrari et al., 2004).

Key Points

- Paratesticular rhabdomyosarcoma arises from the testicular tunics, epididymis, or the spermatic cord.
- In general, patients with paratesticular rhabdomyosarcoma enjoy a favorable prognosis in part because of the following: more than 80% are stage I at presentation, more than 90% are embryonal histology, and there are better-

than-expected outcomes for patients with alveolar histology.

- Patients suspected of having a paratesticular tumor should always be explored with an inguinal incision.
- Tumors in children greater than age 10 years require staging RPLND in COG protocols because of a higher retroperitoneal failure rate.

Perineal Rhabdomyosarcoma

RMS of the perineum (Fig. 54.8) and perianal region (PRMS) is very rare and constitutes fewer than 2% of all RMS cases. The initial lesion may be misdiagnosed as a perineal or perirectal abscess, so a high index of suspicion should be maintained (Hill et al., 2002; Raney et al., 1981). Alveolar histology is more common in this location, and these patients more frequently have regional nodes and metastasis (Raney et al., 1990). PRMS patients in general have experienced poor outcomes. IRS-I through IRS-IV trials demonstrated a 5-year OS of 49% with multimodal therapy (Crist et al., 1995).

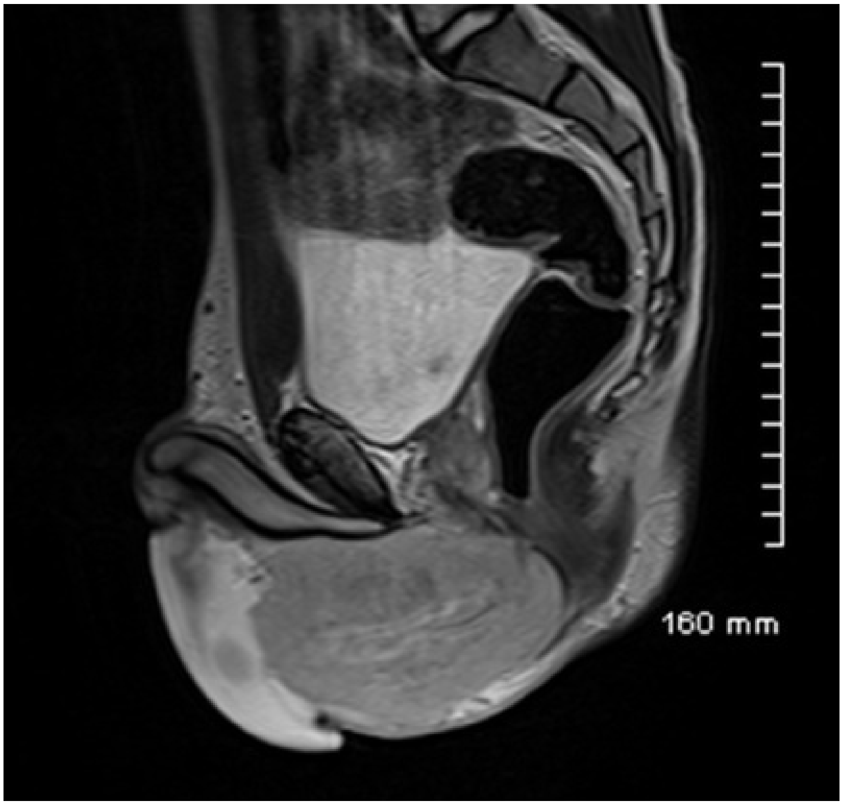

FIG. 54.8 Male patient with large perineal rhabdomyosarcoma. (Courtesy Angela J. Beavers, MD.)

A recent study retrospectively reviewed the outcomes of the Cooperative Soft Tissue Sarcoma Studies between 1986 and 2008 (eligible patients *n* = 32) (Fuchs et al., 2014). All patients received multiagent chemotherapy; for those treated after biopsy, subsequent treatment was decided based on response at 9 weeks.

Local control was then attempted using radiation, surgery, or both. Initial surgery consisted of biopsy (open, needle, punch, or image-guided) in 24 patients; of these 8 had lymph nodes sampled, all of which were positive. Eight patients had primary resection followed by chemotherapy. Consistent with prior reports, the OS and EFS rates were 47%. Positive predictive factors included age younger than 10, tumor size smaller than 5 cm, negative local regional nodes, low IRS group, and embryonal histology.

Infections of the Urinary Tract

Kimberly L. Cooper MD, Gina M. Badalato MD, Matthew P. Rutman MD

Urinary tract infections (UTIs) are common, affect men and women of all ages, vary dramatically in their presentation and sequelae, and are one of the most frequent reasons for prescribing antibiotics. The overwhelming majority of UTIs contribute to varying levels of morbidity yet rarely progress to life-threatening emergencies. In certain populations, however, UTIs can contribute to significant mortality if undiagnosed and untreated. When bacterial virulence increases or host defense mechanisms decrease, bacterial inoculation, colonization, and infection of the urinary tract occur. Careful diagnosis and treatment result in successful resolution of infections in most instances. A better understanding of the pathogenesis of UTIs and the role of host and bacterial factors has improved the ability to identify patients at risk and prevent or minimize sequelae. Recent evidence has proven that urine is not sterile; indeed, in many cases bacteriuria is protective against the development of UTIs. In this era of widespread multidrug-resistant (MDR) bacteria it is crucial that we do not overdiagnose UTIs and expose patients to unnecessary antibiotics. The appropriate management of UTIs includes implementation of antibiotic stewardship, which undoubtedly will have a beneficial impact on global public health. Clinical presentation, in conjunction with analysis of urine samples that are collected in a proper fashion, must be critically determined before recommending antibiotics for bacteriuria and UTIs. Guidelines should be incorporated into clinical practice to improve the use of antibiotics in terms of choice of and duration of therapy. Education of practitioners and patients regarding best practices related to bacteriuria and UTIs is paramount.

Definitions

UTI is an inflammatory response of the urothelium to bacterial invasion that is usually associated with bacteriuria and pyuria.

***Bacteriuria* is the presence of bacteria in the urine.** It has been assumed to be a valid indicator of either bacterial colonization or infection of the urinary tract. Although this is usually true, studies in animals (Hultgren et al., 1985; Mulvey et al., 1998) and humans (Elliott et al., 1985) have indicated that bacteria may be in the urothelium in the absence of bacteriuria. Alternatively, bacteriuria may represent bacterial contamination of an abacteriuric specimen during collection.

***Pyuria*, the presence of white blood cells (WBCs) in the urine, is generally indicative of infection and/or an inflammatory response of the urothelium to bacteria, stones, an indwelling foreign body, or other conditions that can contribute to pyuria. Bacteriuria without pyuria is generally indicative of bacterial colonization without overt infection of the urinary tract. Pyuria without bacteriuria, or sterile pyuria, warrants further evaluation (see the discussion of pyuria in the section on urinalysis).**

Infections are often defined clinically by their presumed site of origin. ***Cystitis* describes a clinical syndrome of dysuria, frequency, urgency, and occasionally suprapubic pain**. These symptoms, although generally indicative of bacterial cystitis, may also be associated with infection of the urethra or vagina or noninfectious conditions such as interstitial cystitis/ painful bladder syndrome, bladder carcinoma, or calculi.

***Acute pyelonephritis* is a clinical syndrome of chills, fever, and flank pain that is accompanied by bacteriuria and pyuria, a combination that is reasonably specific for an acute bacterial infection of the kidney.** Often there are no associated lower urinary symptoms. The term should not be used if flank pain is absent. It may have no morphologic or functional components detectable by routine clinical modalities. There may be significant difficulties in diagnosing spinal cord–injured and elderly patients who may be unable to localize the site of their discomfort.

Chronic pyelonephritis describes a shrunken, fibrosed kidney, diagnosed by morphologic, radiologic, or functional evidence of renal disease that may be postinfectious but is frequently not associated with current (active) UTI. Bacterial infection of the kidney may cause a *focal*, *coarse scar* in the renal cortex overlying a calyx, almost always accompanied by some calyceal distortion (Fig. 55.1), which can be detected radiographically or by gross examination of the kidney. These radiographic changes are identical to those that may be produced by vesicoureteral reflux (VUR) or calyceal stone disease. Less commonly, renal scarring from infection can result in atrophic pyelonephritis or generalized thinning of the renal cortex, with a small kidney appearing radiographically similar to one with postobstructive atrophy (Fig. 55.2). Xanthogranulomatous pyelonephritis (XGP) is a rare form of chronic pyelonephritis often associated with stone disease and characterized by destructive replacement of normal renal parenchyma with granulomatous inflammation; it is associated with ipsilateral loss of renal function (see the section on XGP).

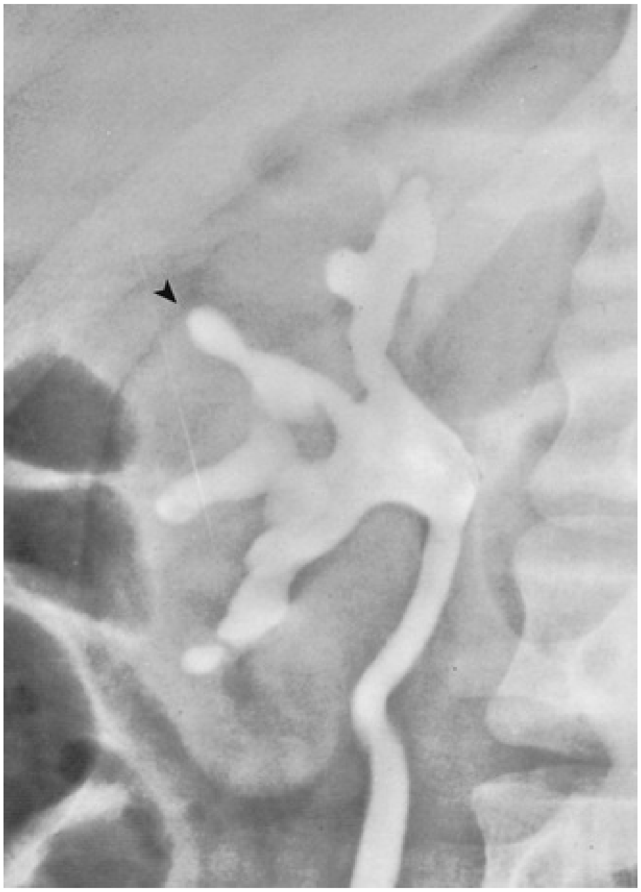

FIG. 55.1 Excretory urogram demonstrates focal, coarse scarring in the right kidney of an 18-year-old girl with a history of many recurrent fevers between 2 months and 2 years of age. A cystogram when the patient was 2 years old established an atrophic left kidney with marked reflux up to the left kidney and slight reflux up to the right kidney. Excretory urography at

the age of 6 years established severe atrophy of the left kidney. She had no infections between the ages of 6 and 15 years. Several reinfections occurred at the age of 15 years, and they ceased with prophylactic therapy. Her blood pressure has remained normal, and her serum creatinine level was 0.9 mg/dL at the age of 18 years. At 21 years of age she stopped antimicrobial prophylaxis for 18 months without infections or introital colonization with Enterobacteriaceae. Note that all calyces are blunted and that one extends to the capsule *(arrowhead)* because of atrophy of the overlying cortex.

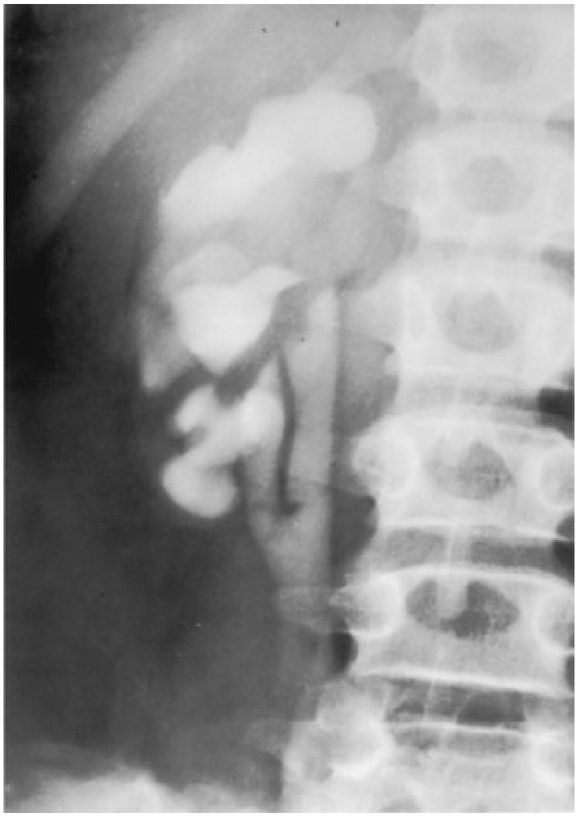

FIG. 55.2 Pyelonephritic atrophy, suggestive of postobstructive atrophy, in a 20-year-old woman with spina bifida, neurogenic bladder, and many episodes of fever and bacteriuria in early childhood. Observe the uniform, regular atrophy of the renal cortex that suggests reflux of bacteria simultaneously into virtually all nephrons. This type of pyelonephritic atrophy is uncommon and is characteristic of obstruction with superimposed infection.

UTIs may also be described in terms of the anatomic or functional status of the urinary tract and the health of the host.

Uncomplicated **describes an infection in a healthy patient with a structurally and functionally normal urinary tract; this often specifically**

refers to the absence of obstruction to any part of the urinary tract. The majority of these patients are women with isolated or recurrent bacterial cystitis or acute pyelonephritis, and the infecting pathogens are usually susceptible to and eradicated by a short course of oral antimicrobial therapy.

A *complicated* infection is associated with factors that increase the chance of acquiring bacteria and decrease the efficacy of therapy (Box 55.1). **The urinary tract is structurally or functionally abnormal, the host is compromised, and/or the bacteria have increased virulence or antimicrobial resistance.**

Box 55.1

Factors That Suggest a Complicated Urinary Tract Infection

- Functional or anatomic abnormality of urinary tract
- Male gender
- Pregnancy
- Elderly patient
- Diabetes
- Immunosuppression
- Childhood urinary tract infection
- Recent antimicrobial agent use
- Indwelling urinary catheter
- Urinary tract instrumentation
- Hospital-acquired infection
- Symptoms for more than 7 days at presentation

Data from Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology*, Philadelphia, 2002, Lippincott Williams & Wilkins, p 212.

Renal diseases that reduce the concentrating ability of the kidney or voiding dysfunction that alter bladder-emptying capabilities are commonly encountered functional abnormalities. Examples of renal diseases, which mainly affect the tubulointerstitial compartment, include postobstructive nephropathy, sickle cell nephropathy, lithium nephropathy, chronic tubulointerstitial nephritis, and inherited diseases such as medullary cystic kidney disease. Examples of anatomic abnormalities include enlargement of the prostate or congenital or acquired sites of residual urine, such as calyceal or urethral or bladder diverticula. Bladder outlet obstruction, neurogenic bladder, and detrusor underactivity also contribute to functional abnormalities. A complicated infection is frequently caused by multidrug-resistant bacteria.

***Chronic*, although implying long time frames,** is a poor term that should be avoided in the context of UTIs, except for chronic pyelonephritis or bacterial prostatitis, because the duration of the infection is not defined.

UTIs may also be defined by their relationship to other UTIs:

- A ***first*** or ***isolated*** infection is one that occurs in an individual who has never had a UTI or has one remote infection from a previous UTI.
- An ***unresolved*** infection is one that has not responded to antimicrobial therapy and is documented to be the same organism with a similar resistance profile.
- A ***recurrent*** infection is one that occurs after documented, successful resolution of an antecedent infection. Consider these two different types of recurrent infection:
    1. *Reinfection* describes a new event associated with reintroduction of bacteria into the urinary tract.
    2. *Bacterial persistence* refers to a recurrent UTI caused by the same bacteria reemerging from a focus within the urinary tract, such as an infectious stone or the prostate. *Relapse* is frequently used interchangeably. These definitions require careful clinical and bacteriologic assessment and are important because they influence the type and extent of the patient's evaluation and treatment.

***Antimicrobial prophylaxis* (AP) is the attempted prevention of reinfections of the urinary tract by the administration of antimicrobial drugs.** If the term is used correctly in reference to the urinary tract, it can be assumed that bacteria have been eliminated before prophylaxis is begun. **Surgical AP entails**

administration of an antimicrobial agent before and for a *limited* time after a procedure to prevent local or systemic postprocedural infections (see the later section on American Urological Association (AUA) guidelines for prophylaxis).

***Antimicrobial suppression* is the attempted prevention of growth of a focus of bacterial persistence that cannot be eradicated.**

Domiciliary* or *outpatient UTIs occur in patients who are not hospitalized or institutionalized at the time they become infected.

***Nosocomial* or *health care–associated UTIs* occur in patients who are hospitalized or institutionalized**.

Catheter-associated UTIs (CAUTIs) occur within that population of patients with indwelling bladder drainage catheters. They are cumulatively the most common cause of secondary bacteremia and are associated with increased morbidity and mortality (Flores-Mireles et al., 2015). Prolonged catheterization, female gender, advanced age, and diabetes represent risk factors for developing a CAUTI (Chenoweth et al., 2014) (see the later section on CAUTIs).

Key Points: Definitions

- Bacteriuria and pyuria are not synonymous with a UTI.
- UTIs are classified based on their presumed site of origin.
- UTIs can be uncomplicated (occurring in healthy patients with normal urinary tracts) or complicated (associated with factors that increase the likelihood of bacteriuria and decrease the efficacy of therapy).

Incidence and Epidemiology

UTI-related complaints are among the most common primary diagnoses for women visiting the emergency department in the United States (Foxman, 2014; Niska et al., 2010). **In 2007 in the United States alone, there were an estimated 10.5 million office visits for UTI-related complaints (accounting for a total of 0.9% of all ambulatory visits), and 2 to 3 million visits to the emergency room** (Schappert, 2011). **Nearly 30% of women have had a symptomatic UTI requiring antimicrobial therapy by age 24, and almost half of all women experience a UTI during their lifetime** (Foxman, 2002). Moreover, 11% of women over the age of 18 have one UTI annually.

Given the frequency of this problem, the associated **financial impact is staggering.** In the United States the direct and indirect costs for the treatment of UTIs annually was estimated to be $2.3 billion in 2010 (Foxman, 2010). For each of these infections, the cost in treating an antimicrobial-resistant organism is greater than treating susceptible bacterial counterparts (Neidell et al., 2012). Furthermore, as it pertains to acute pyelonephritis, the direct and indirect costs were estimated at $2.14 billion in 2000, which is projected to be $2.9 billion in 2013 (Brown et al., 2005).

The incidence of bacteriuria increases with institutionalization or hospitalization and concurrent conditions (Sourander et al., 1966). **CAUTIs are the most common nosocomial infection,** constituting more than 80% of nosocomial UTIs (Foxman, 2002; Sedor, 1999). **The incidence of UTIs is also elevated during pregnancy and in patients with spinal cord injury (SCI), diabetes, multiple sclerosis, organ transplant recipients, and human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome (AIDS).**

Once a patient has an infection, he or she is likely to develop subsequent infections. In fact, historical data by Mabeck originally established that the probability of recurrent UTIs increases with the number of previous infections (Mabeck, 1972). More recent cohort analyses have verified this trend among diverse populations (Foxman, 2014). First, the risk of recurrence is particularly high among young, sexually active women. In a prospective trial following 285 college women after their first UTI, the risk of a second infection was 24% within the 6-month follow-up period (Foxman et al., 2000). In another study examining a group of 796 women starting a new method of contraception, subset analysis showed that those women with a history of 2 or more previous UTIs had 2 to 5 times the risk of recurrence at 1 year compared with counterparts who only had 1 or no previous infections (Hooton et al., 1996). Postmenopausal women with a history of UTIs are similarly at increased risk of recurrence. A 2012 double-bind, non-inferiority study by Beerepoot et al. compared daily trimethoprim-sulfamethoxazole (TMP-SMX) versus lactobacilli prophylaxis among 252 postmenopausal women with approximately 7 symptomatic UTIs in the preceding year. At 12 months, a total of 69.3% recurred in the antibiotic arm compared with 79.1% in the probiotics group, with the mean number of recurrences in the 12-month follow-up period being 2.9 and 3.3, respectively (Beerepoot et al., 2012). Last, among men treated in an ambulatory setting for a UTI within the Veteran Affairs system, the risk of recurrence at 30 days was 4.1% in one retrospective study (Drekonja et al., 2013). Overall, these data examining different demographic groupings underscore the finding that populations with a track record of UTIs do have predisposition to recur.

When women with recurrent bacteriuria were observed after treatment, about one-sixth (37 of 219) had a very high recurrence rate (2.6 infections per year), whereas the remaining women had a recurrence rate of only 0.32 per year (Mabeck, 1972). Similar separation was seen in a prospective study, in which only 28.6% of 60 women who experienced their first symptomatic UTI had recurrent infections over the first 18 months of observation, as opposed to recurrences in 82.5% of 106 women who had had previous UTIs (Harrison, 1974). **Other investigators also have found that the probability of recurrent UTIs increases with the number of previous infections and decreases in inverse proportion to the elapsed time between the first and the second infections** (Mabeck, 1972). Of these recurrent infections, 71% to 73% are caused by reinfection with different organisms, rather than recurrence with the same organism (Guttmann, 1973; Mabeck, 1972).

The sequelae of complicated UTIs are substantial. It is well established in the presence of obstruction, infection stones, diabetes mellitus, and other risk factors that UTIs in adults can lead to progressive renal damage (Freedman, 1975). **The long-term effects of uncomplicated recurrent UTIs are not completely known, but, so far, no association between recurrent infections and renal scarring, hypertension, or progressive renal azotemia has been established** (Asscher et al., 1973; Freedman, 1975).

Key Points: Incidence and Epidemiology

- UTIs are the most common bacterial infection and, as such, make a significant impact on health care costs.
- The incidence of bacteriuria increases with institutionalization/hospitalization as well as with pregnancy and certain comorbidities that alter lower urinary tract function or cause immunosuppression.
- No clear association has been described between recurrent uncomplicated UTIs and renal sequelae such as scarring, hypertension, or progressive renal insufficiency.

Pathogenesis

UTIs occur as a result of interactions between the uropathogen and the host. Successful infection of the urinary tract is determined in part by the virulence factors of the bacteria, the inoculum size, and the inadequacy of host defense mechanisms. These factors also play a role in determining the ultimate level of colonization and damage to the urinary tract. Whereas increased bacterial virulence appears to be necessary to overcome strong host resistance, bacteria with minimal virulence factors are able to infect patients who are significantly compromised.

Routes of Infection

Ascending Route

Most bacteria enter the urinary tract from the bowel and skin reservoir via ascent through the urethra into the bladder. Adherence of pathogens to the introital and urothelial mucosa plays a significant role in ascending infections. This route is further enhanced in individuals with significant soilage of the perineum with feces, women who use spermicidal agents (Foxman, 2002; Handley et al., 2002; Hooton et al., 1996), and patients with intermittent or indwelling catheters.

Most episodes of pyelonephritis are caused by retrograde ascent of bacteria from the bladder through the ureter to the renal pelvis and parenchyma. Although reflux of urine is probably not required for ascending infections, edema associated with cystitis may cause sufficient changes in the ureterovesical junction to permit reflux (Fig. 55.3). Once the bacteria are introduced into the ureter, they may ascend to the kidney unaided. **However, this ascent would be greatly increased by any process that interferes with the normal ureteral peristaltic function. Gram-negative bacteria and their endotoxins, as well as pregnancy, ureteral obstruction, and high lower tract pressures have a significant antiperistaltic effect.**

FIG. 55.3 Bacterial adherence in ascending urinary tract infections. (Modified from Glover M, Moreira CG, Sperandio V, et al.: Recurrent urinary tract infections in healthy and nonpregnant women. *Urological Sci* 25:1, 2014, pp 1–8.)

Bacteria that reach the renal pelvis can enter the renal parenchyma by means of the collecting ducts at the papillary tips and then ascend upward within the collecting tubules. This process is hastened and exacerbated by increased intrapelvic pressure from ureteral obstruction or VUR, particularly when it is associated with intrarenal reflux.

Hematogenous Route

Infection of the kidney by the hematogenous route is uncommon in normal individuals. However, the kidney is occasionally secondarily infected in patients with *Staphylococcus aureus* bacteremia originating from oral sites or with *Candida fungemia*. Experimental data indicate that infection is enhanced when the kidney is obstructed (Smellie et al., 1975).

Lymphatic Route

Direct extension of bacteria from the adjacent organs via lymphatics may occur in unusual circumstances, such as a severe bowel infection or retroperitoneal abscesses. There is little evidence that lymphatic routes play a significant role in the majority of UTIs.

Urinary Pathogens

Most UTIs are caused by facultative anaerobes usually originating from the bowel flora. Uropathogens such as *Staphylococcus epidermidis* and *Candida albicans* originate from the flora of the vagina or perineal skin (Fig. 55.4).

FIG. 55.4 Relevant bacteria for urological infections. *Anaerobic bacteria not considered (see Grabe et al., 2015, p. 60 for clarification). (From Grabe M, Bartoletti R, Bjerklund Johansen TE, et al: *Guidelines on urological infections*, 2015 (website): https://uroweb.org/wp-content/uploads/19-Urological-infections_LR2.pdf.)

***E. coli* is by far the most common cause of UTIs, accounting for 85% of community-acquired and 50% of hospital-acquired infections.** Other gram-negative Enterobacteriaceae, including *Proteus* and *Klebsiella*, and gram-positive *Enterococcus faecalis* and *Staphylococcus saprophyticus* are responsible for the remainder of most community-acquired infections. **Nosocomial infections** are caused by *E. coli, Klebsiella, Enterobacter, Citrobacter, Serratia, Pseudomonas aeruginosa, Providencia, E. faecalis,* and *Staphylococcus epidermidis* (Kennedy et al., 1965). Less common organisms such as *Gardnerella vaginalis, Mycoplasma* species, and *Ureaplasma urealyticum* may infect patients, some of whom have intermittent or indwelling catheters (Fairley, 1989; Josephson et al., 1988). *U. urealyticum* and *M. hominis* have been identified in the urine of women with chronic urinary symptoms but negative standard urine cultures; antibiotic treatment targeted at these organisms has resulted in improvement in symptoms (Baka et al., 2009; Potts et al., 2000). Within the intensive care unit, where virtually all patients who develop a UTI have indwelling catheters, the most frequent pathogens include *Escherichia coli, Pseudomonas aeruginosa*, enterococci, and *Candida albicans*, with species distribution and resistance patterns differing considerably among institutions and regions (Bagshaw, 2006).

With the development of more sophisticated urine culture techniques and the identification of the urinary microbiome (see the section on microbiome), several emerging uropathogens have been identified. Although some may suggest these organisms are part of the microbiome, patients who have these emerging pathogens may be symptomatic and require treatment. *Aerococcus urinae* is a rare pathogen that causes UTIs in older adults with significant comorbidities, including some urologic malignancies (Higgins, 2017). *A. urinae* is often mistaken for *Staphylococcus, Streptococcus*, and *Enterococcus* spp. Another emerging pathogen, *Raoultella planticola*, is a gram-negative rod that has been associated with UTIs in immunocompromised patients (Skelton et al., 2017). *Myroides odoratimimus,* a gram-negative rod commonly found in environmental sources such as soil, has been identified as the causative agent in UTIs in immunocompromised patients and is particularly dangerous because of its extensive drug resistance (Licker et al., 2018).

E. coli strains mediating extraintestinal infections are typically grouped into broad phylogenetic classes by multiplex polymerase chain reaction (Clermont et al., 2000), where 70% of uropathogenic *E. coli* (UPEC) isolates fall into the B2 group (Johnson et al., 2001). More recent studies have used multilocus sequence typing to further define and characterize *E. coli* strains mediating UTI and other infections at the level of “sequence type.” ***E. coli*** **sequence type ST131 (serotype O25b:H4) merits special attention as a rapidly emerging cause of multidrug-resistant infections, including UTI** (Johnson et al., 2010; Kudinha et al., 2013). Although first noted for extended-spectrum β-lactamases (ESBLs), fluoroquinolone resistance is a hallmark phenotype among ST131 isolates. **The prevalence of infecting organisms is influenced by the patient's age.** For example, *S. saprophyticus* is recognized as causing approximately 10% of symptomatic lower UTIs in young, sexually active females (Latham et al., 1983), whereas it rarely causes infection in males and elderly individuals.

Fastidious Organisms

Anaerobes in the Urinary Tract

Symptomatic anaerobic infections of the urinary tract are uncommon. However, the distal urethra, perineum, and vagina are normally colonized by anaerobes. Whereas 1% to 10% of voided urine specimens are positive for anaerobic organisms (Finegold, 1977), anaerobic organisms found in suprapubic aspirates are much more unusual (Gorbach and Bartlett, 1974). Clinically symptomatic UTIs in which only anaerobic organisms are cultured are rare, although they may frequently be a contaminant in midstream urine cultures (Hooton et al., 2013). Nevertheless, **these organisms must be suspected as causative when a patient with persistent bladder irritative symptoms has cocci or gram-negative rods seen on microscopic examination of the centrifuged urine** (catheterized, suprapubic aspirated, or voided midstream urine) **and routine quantitative aerobic cultures fail to grow organisms** (Ribot et al., 1981).

Anaerobic organisms are frequently found in cases of enteric fistualization with the urinary tract or in **suppurative infections** of the genitourinary (GU) system. In one study of suppurative GU infections in males, 88% of scrotal, prostatic, and perinephric abscesses included anaerobes among the infecting organisms (Bartlett and Gorbach, 1981). The organisms found are usually *Bacteroides* species, including *B. fragilis*, *Fusobacterium* species, anaerobic cocci, and *Clostridium perfringens* (Finegold, 1977). The growth of clostridia may be associated with cystitis emphysematosa (Bromberg et al., 1982).

Mycobacterium tuberculosis and Other Nontuberculous Mycobacteria

Mycobacterium tuberculosis and other nontuberculous mycobacteria may be found in the urinary tract (Brooker and Aufderheide, 1980; Thomas et al., 1980). Urinary tuberculosis (UTB) most commonly occurs with hematuria (either gross hematuria, microhematuria, and/or sterile pyuria), storage symptoms, and/or dysuria, with or without systemic symptoms such as fever and weakness. Diagnosis and subsequent treatment are often delayed because of nonspecific symptoms, potentially contributing to impaired renal function and eventual renal failure. Polymerase chain reaction for *M. tuberculosis* has replaced acid-fast staining as the ideal method of diagnosis (Altiparmak et al., 2015; Figueiredo and Lucon, 2008; Ghaleb et al., 2013).

Chlamydia

Chlamydiae are not routinely grown in aerobic culture but have been implicated in GU infections.

Bacterial Virulence Factors

Virulence characteristics play a role in determining if an organism will invade the urinary tract and the subsequent level of infection within the urinary tract. It is generally believed that uropathogenic strains resident in the bowel flora, such as UPEC, can infect the urinary tract not only by chance but also by the expression of virulence factors that enable them to adhere to and colonize the perineum and urethra and migrate to the urinary tract, where they establish an inflammatory response in the urothelium (Moreno et al., 2008; Schaeffer et al., 1981; Schlager et al., 2002; Yamamoto et al., 1997). The same virulence factors can be found on bacterial strains that cause recurrent UTI in patients (Foxman et al., 1995). Some of these virulence determinants are located on 1 of approximately 20 UPEC-specific pathogenicity-associated islands (PAIs) ranging in size from 30 to 170 kb. These PAIs collectively increase the size of the pathogen genome by about 20% over a commensal strain. UPEC phylogroups (A, B1, B2, and D) have been defined based on the presence of genomic PAIs and the expression of associated virulence factors such as adhesions, toxins, surface polysaccharides, flagella, and iron-acquisition systems (Bien et al., 2012).

Early Events in Uropathogenic *E. coli* Pathogenesis

The steps of UPEC pathogenesis include (1) UPEC colonization of the periurethral and vaginal tissue as well as the urethra; (2) ascending infection into the bladder lumen and within the urine; (3) adherence to the surface urothelium and interaction with the bladder epithelial cell defense mechanism; (4) biofilm elaboration; (5) invasion and replication by forming bladder Intracellular Bacterial Communities (IBCs), in which quiescent intracellular reservoirs (QIRs) can form and stay dormant in the underlying urothelium; (6) and, in some cases, renal colonization and host tissue damage with high risk for sepsis (Terlizzi et al., 2017; Fig. 55.5).

FIG. 55.5 Uropathogenic *E. coli* (UPEC). UPEC attaches to the uroepithelium through type 1 pili, which bind the receptors uroplakin Ia and IIIa; this binding stimulates unknown signalling pathways (indicated by the question mark) that mediate invasion and apoptosis. Binding of type 1 pili to α3β1 integrins also mediates internalization of the bacteria into superficial facet cells to form intracellular bacterial communities (IBCs) or pods. Exfoliation of the uroepithelium exposes the underlying transition cells for further UPEC invasion, and the bacteria can reside in these cells as quiescent intracellular reservoirs (QIRs) that may be involved in recurrent infections. (Modified from Croxen MA, Finlay BB. Molecular mechanisms of *Escherichia coli* pathogenicity. *Nat Rev Microbiol* 8:26–38, 2010.)

Bacterial Adherence

Bacterial adherence to vaginal and urothelial epithelial cells is an essential step in the initiation of UTIs. This interaction is influenced by the adhesive characteristics of the bacteria, the receptive characteristics of the epithelial surface, and the fluid bathing both surfaces. Bacterial adherence is a specific interaction that plays a role in determining the organism, the host, and the site of infection. Portions of this section on bacterial adherence have been published elsewhere (Schaeffer et al., 1981).

Bacterial Adhesins.

UPEC expresses a number of adhesins that allow it to attach to urinary tract tissues (Mulvey, 2002). These adhesins are classified as either **fimbrial** or **afimbrial,** depending on whether the adhesin is displayed as part of a rigid fimbria or pilus. Bacteria may produce a number of antigenically and functionally different pili on the same cell; others produce a single type; in some, no pili are seen (Klemm, 1985). A typical piliated cell may contain 100 to 400 pili. The pilus is usually 5 to 10 nm in diameter, is up to 2 µm long, and appears to be composed primarily of subunits known as *pilin* (Klemm, 1985). Pili are defined functionally by their ability to mediate hemagglutination of specific types of erythrocytes. The most well-described pili are types 1, P, and S.

Type 1 (Mannose-Sensitive) Pili.

Type 1 pili are commonly expressed on nonpathogenic and pathogenic *E. coli.* Type 1 pili consist of a helical rod composed of repeating FimA subunits joined to a 3-nm–wide distal tip structure containing the adhesin FimH (Jones et al., 1995). These pili mediate hemagglutination of guinea pig erythrocytes (Duguid et al., 1966). The reaction is inhibited by the addition of mannose; thus type 1 pili are termed *mannose-sensitive hemagglutination* (MSHA) (Reid and Sobel, 1987; Svenson et al., 1984).

The role of type 1 pili as a virulence factor in UTIs has been established. This evidence has been obtained (1) from the analysis of bacteria isolated from the urine of patients with UTIs, which were found to express mannose-sensitive (MS) adhesins (Ljungh and Wadstrom, 1983); (2) from studies with animal models (Fader and Davis, 1982, Hagberg et al., 1983a,b; Hultgren et al., 1985; Iwahi et al., 1983) in which inoculation of type 1 piliated organisms into the bladder resulted in significantly more colonization of the urinary tract than inoculation of nonpiliated organisms; and (3) from the observation that anti–type 1 pili antibodies and competitive inhibitors such as methyl-α-D-mannopyranoside protected mice from contracting UTIs (Aronson et al., 1979; Hultgren et al., 1985). **Studies have demonstrated that interactions between FimH and receptors expressed on the luminal surface of the bladder epithelium are critical for the ability of many UPEC strains to colonize the bladder and cause disease** (Connell et al., 1996; Langermann et al., 1997; Mulvey et al., 1998; Thankavel et al., 1997).

P (Mannose-Resistant) Pili.

P pili confer tropism to the kidney; the designation "P" stands for pyelonephritis (Mulvey, 2002). P pili, which are found in most pyelonephritogenic strains of UPEC, mediate hemagglutination of human erythrocytes that is not altered by mannose and is thus termed *mannose-resistant hemagglutination* (MRHA) (Kallenius et al., 1979). The adhesin PapG, at the tip of the pilus, recognizes the α-D-galactopyranosyl-(1-4)-β-D-galactopyranoside moiety present in the globoseries of glycolipids (Kallenius et al., 1980; Leffler and Svanborg-Eden, 1980), which are found on P blood group antigens and on uroepithelium (Svenson et al., 1983). The *fm* operon of UPEC encodes the type 1 pili and the *pap* operon encodes the P- or Pap-pili. Clinical isolates of UPEC have demonstrated that the fm operon is constitutive and the pap component is part of a PAI that contains other virulence factors (Terlizzi et al., 2017).

Svanborg-Eden and Svennerholm (1978) were the first to report a correlation between bacterial adherence and severity of UTIs. They showed that UPEC strains from girls with acute pyelonephritis had high adhesive ability, whereas strains causing asymptomatic bacteriuria or from the feces of healthy girls had low bacterial adherence. Between 70% and 80% of the pyelonephritic strains, but only 10% of the bowel isolates, had adhesive capacity. Furthermore, P pili were present in 91% of urinary strains causing pyelonephritis, 19% of strains causing cystitis, and 14% of strains causing asymptomatic bacteriuria but only 7% of bowel isolates from healthy children, highlighting the correlation between bacterial adherence and UTIs (Kallenius et al., 1981).

Whereas P pili are strongly associated with pyelonephritis, these virulence factors are not associated with renal scarring and reflux caused by bacterial infection (Vaisanen et al., 1981). Studies suggest minimal correlation between P-piliated *E. coli* strains and recurrent pyelonephritis with gross reflux in girls

(Lomberg et al., 1983). Thus it would appear that P pili in acute pyelonephritis are important mainly in nonrefluxing or minimally refluxing children.

Other Adhesins.

Although pili are important in the initial attachment of UPEC to urothelium, UPEC also expresses a group of afimbrial adhesins (AFA) that are responsible for maintaining this connection (Vigil et al., 2011). One common adhesion TosA was found to be expressed during UTI and was found in 30% of urinary tract samples. Another example includes the iron-regulated adhesion Iha, which mediated adherence to bladder epithelial cells (Johnson et al., 2005).

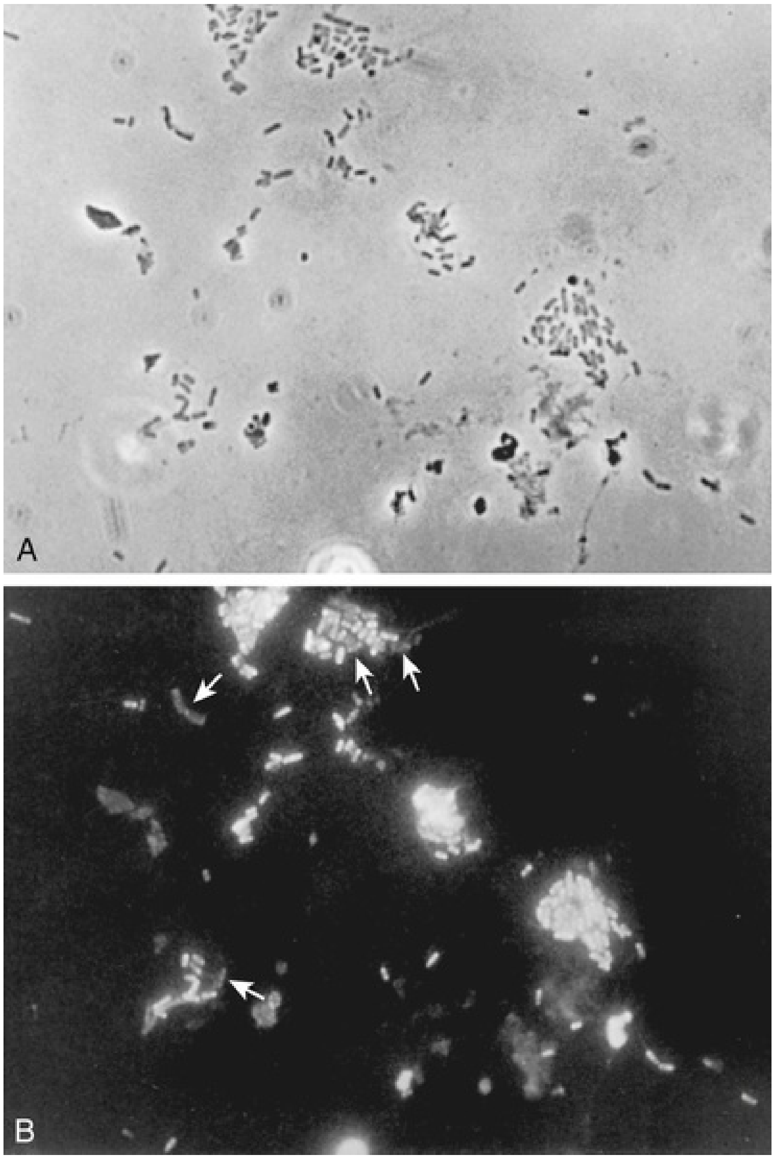
Catch Bonds.

Not surprisingly, UPEC adhesins have evolved to meet the physical dynamics of the urinary tract, and this is best understood for FimH. Using hemagglutination assays and flow cell approaches, **the affinity of *E. coli* expressing specific FimH alleles for erythrocytes was found to be enhanced by shear stress,** and mutations that abolished FimH-erythrocyte interactions in static conditions did not affect dynamic affinities (Thomas et al., 2002). Conversely, static conditions reduced FimH-erythrocyte interactions. Known as *catch bonds*, this fingertrap-like mechanism is mediated by shear-altered interactions between the FimH pili and mannose-binding domains that result in force-induced tightening of the mannose-binding pocket (Le Trong et al., 2010). Similar shear-enhanced binding now appears widespread in biology and includes *E. coli* P-fimbriae (reviewed in Sokurenko et al., 2008). The implications of catch bonds for UPEC adherence and UTI pathogenesis are obvious. **Enhanced adherence in the presence of shear would promote UPEC retention in the urethra and bladder during voiding and in the ureters against peristalsis. In the absence of shear, reduced FimH affinity would facilitate diffusion and thereby promote ascending infection.**

Phase Variation of Bacterial Pili in vivo

Assessment of pili production by clinical *E. coli* isolates demonstrates that environmental growth conditions can produce rapid changes in pilus expression (Duguid et al., 1966; Goransson and Uhlin, 1984; Hultgren et al., 1986), wherein cells switch back and forth between piliated and nonpiliated phases (Eisenstein, 1981). For example, some bacteria grown in a broth medium express pili, whereas the same strain grown on the same medium in a solid state will cease production of pili. **This process, called *phase variation*, can also occur in vivo and has obvious biologic and clinical implications.** For example, the presence of type 1 pili may be advantageous to the bacteria for adhering to and colonizing the bladder mucosa but disadvantageous because the pili enhance phagocytosis and killing by neutrophils (Silverblatt et al., 1979).

Studies in humans using indirect immunofluorescence of fresh urine bacteria have confirmed in vivo expression and phase variation of pili. Analysis of the urine of adults with lower UTI detected type 1 pili in 31 of 41 specimens and P pili in 6 of 18 specimens (Kisielius et al., 1989). The piliation status of the bacterial population in the urine was heterogeneous, varying from predominantly piliated to a mixture of piliated and nonpiliated cells (eFig. 55.6). Strains isolated from different sites in the urogenital tract showed variation in the state of piliation.



EFIG. 55.6 Phase-contrast micrograph (A) and immunofluorescence micrograph (B) of a sample stained with antiserum to type 1 pili of strain I-49 and with fluorescein isothiocyanate–conjugated second antibody against nonadherent *Escherichia coli* in the urine of a patient with acute urinary tract infection show a mixture of piliated and nonpiliated (*arrows* in B) cells. (From Kisielius PV, Schwan WR, Amundsen SK, et al.: In vivo expression and variation of *Escherichia coli* type 1 and P pili in the urine of adults with acute urinary tract infections. *Infect Immun* 57:1656–1662, 1989.)

This process of phase variation has obvious biologic and clinical implications. For example, the presence of type 1 pili may be advantageous to the bacteria for initially adhering to and colonizing the bladder mucosa. Subsequently, type 1 pili may be unnecessary for strains in suspension in urine and in fact detrimental because they enhance apoptosis, phagocytosis, and killing by neutrophils (Mulvey et al., 1998; Silverblatt et al., 1979). In the kidney, P pili may then take over as the primary mediator of bacterial attachment via their binding to the glycolipid receptors (Stapleton et al., 1995).

Epithelial Cell Receptivity

Vaginal Cells

The significance of epithelial cell receptivity in the pathogenesis of ascending UTI has been studied initially by examining adherence of *E. coli* to vaginal epithelial cells and uroepithelial cells collected from voided urine specimens. Fowler et al. (1977) established that certain indigenous microorganisms (e.g., lactobacilli, *S. epidermidis*) avidly attached themselves to washed epithelial cells in large numbers. When vaginal epithelial cells were collected from patients susceptible to reinfection and compared with such cells obtained from controls resistant to UTI, the *E. coli* strains that cause cystitis adhered much more avidly to the epithelial cells from the susceptible women. **These studies established increased adherence of pathogenic bacteria to vaginal epithelial cells as the first demonstrable biologic difference that could be shown in women susceptible to UTI.**

Subsequently, Schaeffer et al. (1981) **confirmed these vaginal differences in women, but in addition they observed that the increased bacterial adherence was also characteristic of buccal epithelial cells.** As can be seen in Fig. 55.7, there is a striking similarity in the ability of both cell types to bind to the same *E. coli* strain. In addition, there was a significant relationship between vaginal cell and buccal cell receptivity. Seventy-seven different *E. coli* strains were tested for their ability to bind to vaginal and buccal epithelial cells. A direct nonlinear relationship between buccal and vaginal adherence in controls and patients was confirmed for urinary, vaginal, and anal isolates. Thus high vaginal cell receptivity was associated with high buccal cell receptivity.

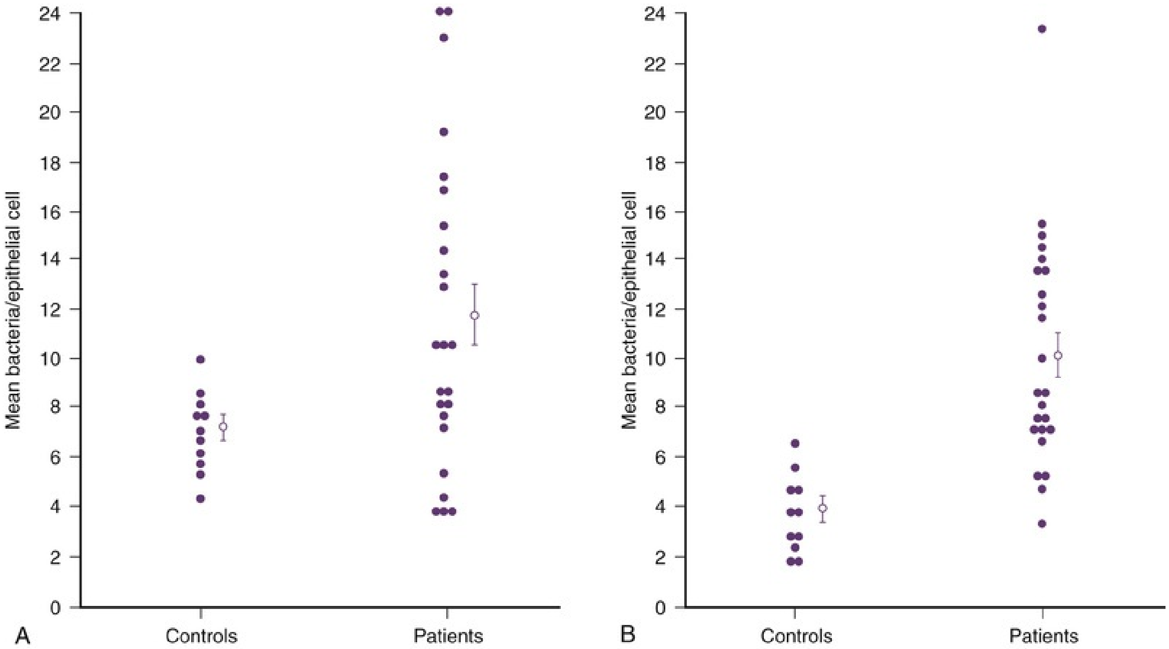


FIG. 55.7 In vitro adherence of *Escherichia coli* to vaginal (A) and buccal (B) cells from healthy controls and patients with recurrent urinary tract infections. Values represent an average of 14 (A) and 11 (B) determinations in each individual. The *open circles* and *bars* represent the means + standard error of the mean. (Data from Schaeffer AJ, Jones JM, Dunn JK: Association of in vitro *Escherichia coli* adherence to vaginal and buccal epithelial cells with susceptibility of women to recurrent urinary tract infections. *N Engl J Med* 304:1062–1066, 1981.)

These observations emphasize that the increase in receptor sites for UPEC on epithelial cells from women with recurrent UTIs is not limited to the vagina and thus suggest that a genotypic trait for epithelial cell receptivity may be a major susceptibility factor in UTIs. This concept was extended by examining the human leukocyte antigens (HLAs), which are the major histocompatibility complex in humans and have been associated statistically with many diseases (Schaeffer et al., 1994). The A3 antigen was identified in 12 (34%) of the patients, which is significantly higher than the 8% frequency observed in healthy controls. Thus HLA-A3 may be associated with increased risk of recurrent UTIs.

Variation in Receptivity.

A small variation in vaginal cell and buccal cell receptivity may be observed from day to day in healthy controls. Adherence ranges from 1 to 17 bacteria per cell and appears to be cyclic and repetitive. When adherence was correlated with the days of a woman's menstrual cycle, higher values were noted in the early phase, diminishing shortly after the time of expected ovulation (day 14). The number of bacteria per epithelial cell often correlated with the value obtained on the same day of the menstrual cycle 1 or 2 months previously. Premenopausal women are particularly susceptible to attachment of UPEC and nonpathogenic lactobacilli at certain times during the menstrual cycle and to *E. coli* during the early stages of pregnancy. **The importance of such hormones as estrogens in the pathogenesis of UTI is therefore a matter of great interest, especially because the clinical urologist may see women who have recurrent cystitis at regular intervals, possibly in response to these hormonal changes.**

Reid and Sobel (1987) found that uropathogens attached in larger numbers to uroepithelial cells from women older than 65 years of age than to cells from premenopausal women 18 to 40 years of age. Raz and Stamm (1993) noted that **susceptibility to recurrent UTI was increased by the lowered estrogen levels found in the postmenopausal women and that estrogen replacement decreased uropathogenic bacterial colonization and the incidence of UTI.**

Blood group antigens and carbohydrate structures bound to membrane lipids or proteins also constitute an important part of the uroepithelial cell membrane. The **presence or absence of blood group determinants on the surface of uroepithelial cells may influence an individual's susceptibility to a UTI**. Sheinfeld et al. (1989) determined the blood group phenotypes in women with recurrent UTI and compared them with those of age-matched women controls. There is a higher frequency of Lewis nonsecretor Le(a+b−) and recessive Le(a−b−) phenotypes among women with recurrent UTIs. The nonsecretor status has also been associated with female acute uncomplicated pyelonephritis, especially in premenopausal women (Ishitoya et al., 2002). Stapleton et al. (1995) have shown that unique *E. coli*–binding glycerides are found in vaginal epithelial cells from nonsecretors but not from secretors. **These studies individually and collectively support the concept that there is an increased epithelial receptivity for *E. coli* on the introital, urethral, and buccal mucosa that is characteristic of women susceptible to recurrent UTIs and may be a genotypic trait.**

The possibility that vaginal mucus may influence bacterial receptivity was investigated by Schaeffer et al. (1994). Type 1 piliated *E. coli* bound to all of the vaginal fluid specimens (Venegas et al., 1995). The binding capacity of vaginal fluid from women colonized with *E. coli* in vivo was greater than that from noncolonized women (Schaeffer and Stuppy, 1999). The importance of vaginal fluid in bacteria/epithelial cell interactions was investigated in an in vitro model that measured the effect of vaginal fluid on the binding of bacteria to an epithelial cell line (Gaffney et al., 1995). Vaginal fluid from colonized women enhanced binding of bacteria to epithelial cells. Conversely, vaginal fluid from noncolonized women inhibited adherence. Thus the **vaginal fluid appears to influence adherence to cells** and, presumably, vaginal mucosal colonization. Subsequent studies demonstrated that secretory IgA is the primary glycoprotein responsible for vaginal fluid receptivity (Rajan et al., 1999).

Bladder Cells

FimH binds mannosylated residues on the uroplakin molecules covering bladder superficial epithelial cells. The luminal surface of the bladder is lined by umbrella cells. The apical surfaces of umbrella cells appear as a quasi-crystalline array of hexagonal complexes composed of four integral membrane proteins known as *uroplakins* (Sun, 1996). In vitro binding assays have shown that two of the uroplakins, UPIa and UPIb, can specifically bind UPEC expressing type 1 pili (Wu et al., 1996). High-resolution freeze-fracture electron microscopy has shown that the tips of these pili, including the adhesins, are buried in the central cavity of the uroplakin hexameric rings (Mulvey et al., 2000; Fig. 55.8). **Thus FimH-mediated binding to the bladder epithelium is the initial step in the intricate cascade of events leading to UTIs.** Immediate urothelial responses to UPEC may be triggered by uroplakins because FimH binding to UPIb was shown to result in phosphorylation of UPIII and subsequent UPIII-mediated increases in intracellular calcium (Thumbikat et al., 2009).

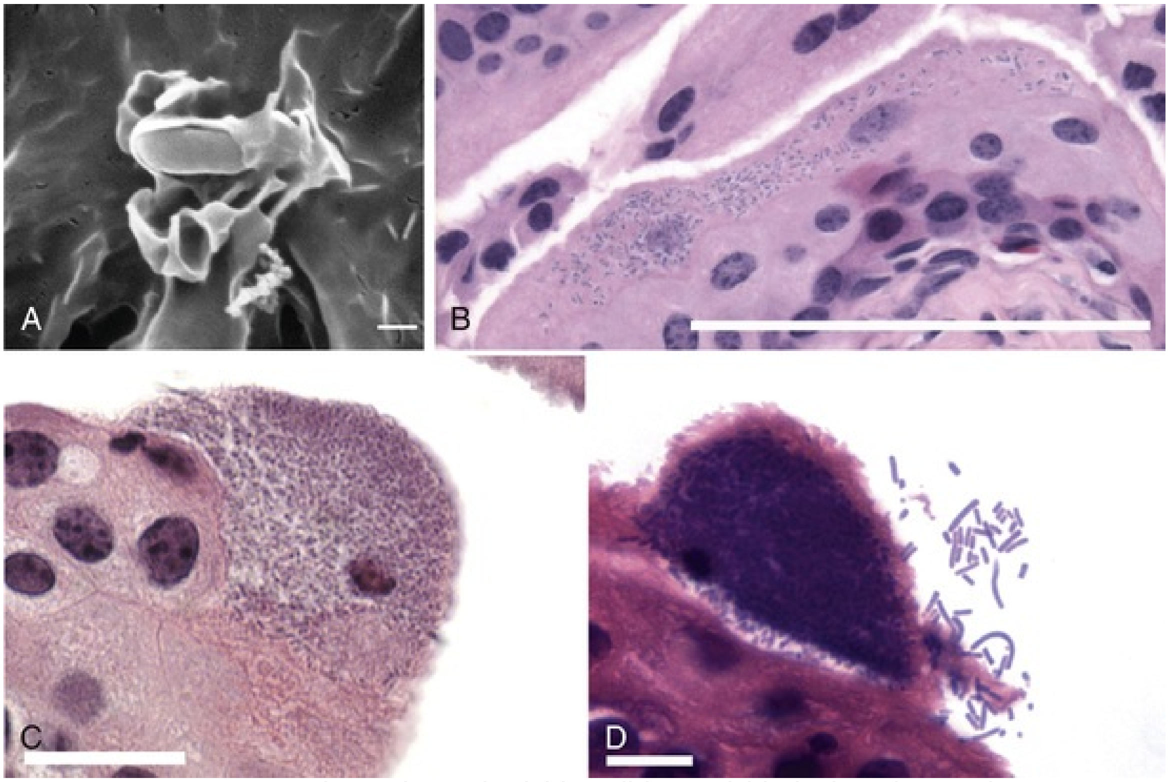

FIG. 55.8 Uropathogenic *Escherichia coli* (UPEC) binds, invades, and multiplies inside the superficial cells of the bladder epithelium. (A) Scanning electron microscopy shows a single UPEC bound to the surface of a bladder cell. Type 1 pilus–mediated contact between bacterium and host cell initiates signaling cascades in the bladder cell, leading to localized actin rearrangements and membrane protrusions around the bacterium. Scale bar, 0.5 µm. (B) Once inside the bladder superficial cells, UPEC rapidly multiplies to form disordered bacterial clusters in the host cell cytoplasm, called an early intracellular bacterial community (IBC). Bacteria are visible as dark-staining rods inside the cell in this hematoxylin and eosin (H&E)-stained thin bladder section. Scale bar, 100 µm. (C) H&E-stained thin bladder section reveals a middle IBC, wherein the constituent bacteria have organized themselves into a biofilm-like state within the bladder cell. Scale bar, 20 µm. (D) A late IBC, visible by H&E staining, is typified by detachment of peripheral bacteria and fluxing of these organisms into the bladder lumen. Scale bar, 10 µm. (From Anderson GG, Martin SM, Hultgren SJ: Host subversion by formation of intracellular bacterial communities in the urinary tract. *Microbes Infect* 6:1094–1101, 2004.)

Uropathogenic *E. coli* Persistence in the Bladder.

Soon after attachment to the epithelium, UPEC is quickly internalized into the bladder superficial cells (Anderson et al., 2004a,b; Martinez and Hultgren, 2002; Fig. 55.9). Invasion into the superficial epithelium of the bladder allows UPEC to establish a new niche in an effort to protect itself from the host innate immune response (Anderson et al., 2004a,b).

FIG. 55.9 Uropathogenic *Escherichia coli* model for acute cystitis, chronic cystitis, and quiescent intracellular reservoir formation: intracellular bacterial community (IBC) formation starts when bacteria attach onto the apical transitional epithelium of the bladder via type 1 pili. These bacteria are then enveloped and invade the epithelium, replicating and forming IBCs. As a host response to infection, the urothelium typically exfoliates, resulting in IBC liberation and IBC recreation in a clonal fashion. IBCs may also progress to quiescent intracellular reservoirs, which are not metabolically active and do not produce a measurable inflammatory response. (Modified from Hannan TJ, Totsika M, Mansfield KJ, et al.: Host-pathogen checkpoints and population bottlenecks in persistent and intracellular uropathogenic *Escherichia coli* bladder infection. *FEMS Microbiol Rev* 3:616e48, 2012.)

Once intracellular, the UPEC organisms rapidly grow and divide within the cell cytosol, forming small clusters of bacteria termed *early intracellular bacterial communities* (IBCs) (Anderson et al., 2004a,b; Justice et al., 2004). As they grow, the bacteria maintain their typical rod shape of approximately 3 µm and form a loosely organized cluster, with microorganisms randomly oriented in the cell cytoplasm. Between 6 and 8 hours after inoculation, early IBCs show a drop in bacterial growth rate, resulting in doubling times greater than 60 minutes, a significant shortening of the bacterial morphology to an average of 0.7 µm, and a phenotypic switch into a biofilm-like community (Justice et al., 2004) Similar bacteria-engorged urothelial cells have been identified in 22% of voided urine specimens from patients with UTI with *E. coli* (Rosen et al., 2007). Importantly, **UPEC isolated from the human IBC-like cells were capable of infecting mice and recapitulating IBCs** (Garofalo et al., 2007).

Biofilms shield bacteria from environmental challenges such as antimicrobial agents and the host immune response (Donlan and Costerton, 2002)**. Characteristics of the biofilm that increase protection include the slower growth rate of the bacteria with associated physiologic changes, expression of factors that inhibit antimicrobial activity, and the inability of the antimicrobial agent to penetrate the biofilm matrix** (Anderson et al., 2004a,b). The biofilm also protects the bacteria from neutrophils because they are unable to effectively penetrate the IBC and engulf the bacteria. In animal models, bacteria on the edge of IBCs eventually detach, differentiate to typical rod morphology, become motile, and then escape the host cell into the bladder lumen in a process called *fluxing* (Mulvey et al., 2001). These bacteria may become highly filamentous, reaching up to 70 µm or greater in length. This process occurs by approximately 24 hours after inoculation (Justice et al., 2004). It is possible that the filaments may help the bacteria evade the immunologic response. Moreover, a large majority of UPEC isolated from women with acute, asymptomatic, or recurrent UTIs have shown the presence of flagellum-mediated movement, which may play an important role in adherence and dispersal during biofilm elaboration (Nakamura et al., 2016; Wright et al., 2005).

The escaped bacteria re-adhere and reinvade superficial cells to lead to second IBC formation. In subsequent rounds, further IBC formation occurs. After a few days, the invasive bacteria become more quiescent. In animal models, the bacteria can persist in this dormant reservoir state for some time before reemerging to cause recurrent UTIs (Anderson et al., 2004a,b). Indeed, in murine UTI, individuals with sterile urine nonetheless may contain thousands of viable UPEC within bladder tissue (Mulvey et al., 2001), suggesting that IBCs may be a transient intermediate in the establishment of stable UPEC reservoirs within the bladder. Exfoliation of superficial urothelial cells (see later) exposes underlying transitional cells. In contrast to the cytosolic UPEC aggregates characteristic of IBCs, UPEC invasion of transitional cells results in membrane-bound bacteria limited to two to four bacteria per cell (Justice et al., 2004). These intracellular UPEC remain quiescent, and thus such transitional cells are referred to as *quiescent intracellular reservoirs* (QIRs) (Mysorekar and Hultgren, 2006). However, chemically perturbing the urothelium to evoke urothelial differentiation caused reemergence of UPEC from QIR marked by significant bacterial proliferation. **Together, these findings suggest that bladder reservoirs of intracellular UPEC may contribute to recurrent UTI in susceptible individuals as the transitional cells undergo differentiation.**

Natural Defenses of the Urinary Tract

Periurethral and Urethral Region

The normal flora of the vaginal introitus, the periurethral area, and the urethra usually contain microorganisms such as lactobacilli, coagulase-negative staphylococci, corynebacteria, and streptococci that form a barrier against uropathogenic colonization (Fair et al., 1970; Marrie et al., 1978; Pfau and Sacks, 1977). Changes in the vaginal environment related to estrogen, cervical IgA (Stamey et al., 1978), and low vaginal pH (Stamey and Timothy, 1975) may alter the ability of these bacteria to colonize. More commonly, however, acute changes in colonization have been associated with use of antimicrobial agents and spermicidal agents that alter the normal flora and increase the receptivity of the epithelium for uropathogens.

Little is known about the factors that predispose patients to urethral colonization with uropathogens. The proximity of the urethral meatus to the vulvar and perianal areas suggests that contamination occurs frequently. The nature of urethral defense mechanisms other than flow of urine is largely unknown. Bacterial multiplication in the normal urethra may be inhibited by the indigenous flora (Chan et al., 1984). Although colonization of the periurethral and urethral regions is prerequisite to most infections, the ability of the organisms to overcome the normal defense mechanisms of the urine and the bladder is clearly pivotal.

Urine

In general, fastidious organisms that normally colonize the urethra will not multiply in urine and rarely cause UTIs (Cattell et al., 1973). In contrast, urine usually supports the growth of nonfastidious bacteria (Asscher, et al. 1973). **Urine from normal individuals may be inhibitory, especially when the inoculum is small** (Kaye, 1968)**. The most inhibitory factors are the osmolality, urea concentration, organic acid concentration, and pH. Bacterial growth is inhibited by either very dilute urine or a high osmolality when associated with a low pH.** Much of the antimicrobial activity of urine is related to a high urea and organic acid content (Solomon et al., 1983). From a clinical perspective, however, these conditions do not appear to significantly distinguish between patients who are susceptible or resistant to infection.

Uromodulin (Tamm-Horsfall protein), a kidney-derived mannosylated protein that is present in an extraordinarily high concentration in the urine (>100 mg/mL), **may play a defensive role by saturating all the mannose-binding sites of the type 1 pili, thus potentially blocking bacterial binding to the uroplakin receptors of the urothelium** (Duncan, 1988; Kumar and Muchmore, 1990).

Bladder

Bacteria presumably make their way into the bladder frequently. Whether small inocula of bacteria persist, multiply, and infect the host depends in part on the ability of the bladder to empty (Cox and Hinman, 1961). Additional factors responsible for defense involve innate and adaptive immunity and exfoliation of epithelial cells.

Immune Response

Pathogen Recognition.

The host recognition of the pathogen is mediated by a series of pathogen-associated molecular pattern receptors (PAMPs), such as Toll-like receptors (TLRs) (Anderson et al., 2004a,b), which provide the link between recognition of invading organisms and development of the innate immune response. TLRs recognize molecular patterns that are conserved among many species of pathogens, such as lipopolysaccharide (LPS) and peptidoglycan (PG), and activate signaling pathways that initiate immune and inflammatory responses to kill pathogens. Superficial bladder epithelial cells express TLR4 on their membranes, which, along with CD14, recognize LPS from the bacteria and activate the innate immune response (Anderson et al., 2004a,b). The newly identified TLR11, which recognizes UPEC and protects the kidneys from ascending infection, is also expressed on uroepithelial cells, as well as renal cells (Zhang et al., 2004).

The innate system response to an infection in the bladder or kidneys is primarily local inflammation. **The innate immune response occurs more rapidly than the adaptive response and involves a variety of cell types, including polymorphonuclear leukocytes, neutrophils, macrophages, eosinophils, natural killer cells, mast cells, and dendritic cells.** In addition, increased transcription of inducible nitric oxide synthase by polymorphonuclear leukocytes results in high levels of nitric oxide and related breakdown products that also have toxic effects on the bacteria (Poljakovic and Persson 2003; Poljakovic et al., 2001). Adaptive immunity involves the specific recognition of pathogens by T and B lymphocytes and production of high-affinity antibodies, a process that occurs 7 to 10 days after infection.

The urinary tract is part of the secretory immune system. In pyelonephritis, IgG and SIgA appear in the urine and may become evident before antibodies are detected in the serum. These antibodies are synthesized locally within the kidney and may enhance bacterial opsonization and ingestion by local phagocytic cells. These antibodies may have further protective function. Svanborg-Eden and Svennerholm (1978) showed that IgG and SIgA derived from the urine of patients with acute pyelonephritis reduced in vitro adherence of the same strain of *E. coli* to uroepithelial cells. Similarly, immunization with *E. coli* P pili resulted in immunoglobulin production in experimental animals that prevented ascending pyelonephritis by reducing the adhesive capacity of the invading autologous uropathogenic *E. coli* (O'Hanley et al., 1983; Roberts and Phillips, 1979).

Toll-Like Receptor Signaling.

Because TLR signaling triggers innate immune responses and mediates innate-adaptive interactions, diverse pathogens target TLR signaling. Consistent with this, TLR modulation has been identified in UPEC. UPEC was found to modulate urothelial inflammatory responses at the levels of nuclear factor-κB (NF-κB) activation and cytokine suppression, and this inflammatory suppression is widespread among clinical *E. coli* strains (Billips et al., 2007; Hunstad et al., 2005; Klumpp et al., 2001). In contrast to bacteria that modulate inflammatory responses through the action of secreted virulence factors, UPEC genetic screens identified genes associated with modification of TLR ligands (Billips et al., 2008; Hunstad et al., 2005). Some UPEC strains even encode direct inhibitors of TLR signaling (Cirl et al., 2008). Together, these findings suggest that **UPEC enhances virulence by modulating inflammatory responses at the level of TLR recognition, thereby extending a "window of opportunity"** to establish infection by evading innate surveillance mechanisms.

Induced Exfoliation.

Mulvey et al. (1998) **demonstrated that exfoliation and excretion of infected and damaged superficial cells is mediated by type 1 piliated bacteria that induce programmed cell death.** By using an in vivo mouse model, it has been demonstrated that mice exhibiting a strong exfoliation response to UPEC infiltration are unlikely to form IBCs (Anderson et al., 2004a,b). However, mice with a much milder exfoliation response tend to form biofilms, which become sequestered in the bladder and presumably could lead to recurrent UTIs. **It has also been shown that many uropathogenic bacteria can suppress NF-κB, increase apoptosis, and decrease the inflammatory responses** (Klumpp et al., 2001)**, a process that could lead to subsequent bacterial invasion into deeper tissues. Indeed, a key reason for the high rate of recurrence of infections in the bladder and resistance to antibiotics is associated with the formation of subepithelial QIRs. Thus in some instances apoptosis may be a bacterial offense maneuver rather than a host defense** (Leatham-Jensen et al., 2016).

Alterations in Host Defense Mechanisms

Obstruction

Obstruction to urine flow at all anatomic levels, whether secondary to anatomic abnormalities or elevated storage pressure, is a key factor in increasing host susceptibility to UTI. Obstruction inhibits the normal flow of urine, and the resulting stasis compromises bladder and renal defense mechanisms. **Stasis also contributes to the growth of bacteria in the urine and their ability to adhere to the urothelial cells.** In the animal model of experimental hematogenous pyelonephritis, the kidney is relatively resistant to infection unless a ureter is ligated. Under these circumstances, only the obstructed kidney becomes infected (Beeson and Guze, 1956). Clinical observations support the role of obstruction in pathogenesis of UTI and in increasing severity of infection. **Minimal episodes of cystitis or pyelonephritis can become life threatening when obstruction to urine flow becomes present.** Although obstruction clearly increases the severity of infection, it need not be a predisposing factor. For example, men with large residual urine may remain uninfected for years.

Vesicoureteral Reflux

Hodson and Edwards (1960) first described the association of VUR, UTI, and renal clubbing and scarring. **Children with high-grade reflux and UTIs usually develop progressive renal damage manifested by renal scarring, proteinuria, and renal failure. Those with a lesser degree of reflux usually improve or completely recover spontaneously or after treatment of the UTI. In adults, the presence of reflux does not appear to decrease renal function unless there is high storage pressure or stasis and concurrent UTIs.**

Underlying Disease

There is a high incidence of renal scarring in patients with underlying conditions that cause chronic interstitial nephritis, almost all of which produce primary renal papillary damage. These conditions include diabetes mellitus, sickle cell disorders, adult nephrocalcinosis, hyperphosphatemia, hypokalemia, analgesic abuse, sulfonamide nephropathy, gout, heavy-metal poisoning, and aging (Freedman, 1979).

Diabetes Mellitus

An increased incidence of asymptomatic bacteriuria and symptomatic UTIs appears to occur in women with diabetes mellitus, but there is no substantial increase among men with diabetes (Forland et al., 1977; Meiland et al., 2002; Ooi et al., 1974; Vejlsgaard, 1973). Some contributory factors to the increased incidence include incomplete bladder emptying, poor glucose control, and impaired immune response (Boyko et al., 2005)

Diabetes appears to predispose the patient to more severe infections. Frequent courses of antibiotics for asymptomatic bacteriuria and symptomatic UTIs in patients with diabetes result in a higher incidence of resistant pathogens (ESBL-positive Enterobacteriaceae, carbapenem-resistant Enterobacteriaceae, and vancomycin-resistant enterococci [VRE]). Multiple studies have investigated the relationship between risk of UTI and glycosuria, but there is no evidence to support this relationship (Johnsson et al., 2013; Rizzi and Trevisan, 2016). One study using antibody-coated bacteria techniques to localize the site of infection showed the upper urinary tract to be involved in nearly 80% of patients with diabetes and UTIs (Forland et al., 1977). This evidence of increasing immunologic response in patients with diabetes who acquire bacteriuria suggests renal parenchymal involvement and a potential increase in morbidity.

Infections are frequently caused by atypical organisms such as yeast and result in upper tract infections and significant sequelae such as emphysematous pyelonephritis, papillary necrosis, perinephric abscess, or metastatic infection (Stapleton, 2002; Wheat, 1980).

Renal Papillary Necrosis

The role of infection in the development and progression of renal papillary necrosis (RPN) is controversial. **Multiple predisposing conditions have been associated with the development of RPN, particularly diabetes, analgesic abuse, sickle cell hemoglobinopathy, and obstruction** (Box 55.2).

Box 55.2

Conditions Associated With Renal Papillary Necrosis

Diabetes mellitus
Pyelonephritis
Urinary tract obstruction
Analgesic abuse
Sickle cell hemoglobinopathies
Renal transplant rejection
Cirrhosis of the liver
Dehydration, hypoxia, and jaundice of infants
Miscellaneous: renal vein thrombosis, cryoglobulinemia, renal candidiasis, contrast media injection, amyloidosis, calyceal arteritis, necrotizing angiitis, rapidly progressive glomerulonephritis, hypotensive shock, acute pancreatitis

Data from Eknoyan G, Qunibi WY, Grissom RT, et al.: Renal papillary necrosis: an update. *Medicine* 61:55, 1982.

Clinically, RPN is a spectrum of disease. Patients may have an acute fulminating illness with rapid progression or may have a chronic disease that is incidentally discovered. Some patients may chronically pass necrotic tissue in their urine (Hernandez et al., 1975), whereas some may never experience papilla loss in the urine (Lindvall, 1978). Retained necrotic papillae may calcify, especially in association with infection. Furthermore, this necrotic tissue may form the nidus for chronic infection. Opportunistic fungal infections have been reported (Juhasz et al., 1980; Madge and Lombardias, 1973; Tomashefski and Abramowsky, 1981; Vordermark et al., 1980). Renal sonography may be useful to diagnose RPN (Buonocore et al., 1980; Hoffman et al., 1982).

The early diagnosis of RPN is important to improve prognosis and reduce morbidity. In addition to chronic infection, patients with analgesic abuse–associated papillary necrosis may have an increased incidence of urothelial tumors; routine urinary cytologic examinations may be helpful to diagnose these tumors early (Jackson et al., 1978). In patients who have analgesic abuse–induced RPN, the disease stabilizes if the analgesic intake is stopped (Gower, 1976). Furthermore, adequate antimicrobial therapy to control infection and early recognition and treatment of ureteral obstruction caused by sloughed necrotic tissue can minimize a decline in renal function. **A patient who suffers from an acute ureteral obstruction caused by a sloughed papilla and who has a concomitant UTI has a urologic emergency.** In this case, immediate removal of the obstructing papilla by stone basket (Jameson and Heal, 1973) or acute drainage of the kidney by ureteral catheter or percutaneous nephrostomy is necessary.

In the case of sickle cell disease, it is particularly important that patients engage with nephrology early to prevent the progression of sickle cell nephropathy, which includes glomerular disease in addition to papillary necrosis. Preventive measures include ensuring adequate fluid intake, blood pressure control, and the use of angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers (ARBs) in patients who have microalbuminuria and/or proteinuria (Gebreselassie et al., 2015).

Other conditions that may increase the susceptibility of the kidney to infection include hypertension and vascular obstruction (Freedman, 1979). The association of renal infection with several other renal diseases, including glomerulonephritis, atherosclerosis, and tubular necrosis, which are not associated with papillary necrosis, does not lead to pyelonephritis and scarring.

Human Immunodeficiency Virus

UTIs are fivefold more prevalent in HIV-positive individuals than in control subjects (Schonwald et al., 1999). The pathologic bacteria include higher rates of *Acinetobacter* and *Salmonella* species in HIV-positive patients. Patients with AIDS (defined by either an AIDS-defining illness and/or CD4 count <200 cells/mm^3) are at higher risk for atypical infections including fungal (*Candida* spp., *Aspergillus* spp., *Cryptococcus neoformans*, and other endemic fungi such as *Histoplasma*), mycobacterial (tuberculosis and nontuberculous mycobacteria), and viral (cytomegalovirus and adenoviruses) infections. Patients with a CD4 count below 200 cells/mm^3 are typically placed on *Pneumocystis* pneumonia prophylaxis; often TMP-SMX (which decreases UTI risk), unless the patient has a sulfa allergy or G6PD deficiency.

Other Conditions That Increase Risk of Urinary Tract Infections

Renal Transplantation

UTIs are among the most common infection sustained by renal transplant recipients, with more than one-third of renal transplant recipients sustaining at least one infection after surgery; they also remain a potential risk factor for poorer graft outcomes (Golebiewska et al., 2011). Transplant recipients are noted to have a higher incidence of infections with bacteria-harboring antibiotic resistance capability and are prone to recurrent episodes of symptomatic infection, likely related to colonization within their urinary tract (Hollyer and Ison, 2017). Exposure to intensified immunosuppression resulting from acute rejection episodes, female gender, advanced age of the recipients, long catheter duration, and cadaveric donor remains the risk factor for recurrent UTIs (Wu et al., 2016).

Menopause

UTIs among women increase in frequency after menopause; the rationale and treatment strategies for this are discussed in subsequent sections.

Pregnancy

See the section entitled *Bacteriuria in Pregnancy* for a complete discussion of this topic.

Spinal Cord Injury With High-Pressure Bladders

Of all patients with bacteriuria, no group compares in severity and morbidity with those who have SCI. Nearly all these patients require catheterization early after their injuries because of bladder overactivity or flaccidity, and significant numbers develop ureterectasis, hydronephrosis, reflux, and renal calculi. Bacteriologic and urodynamic advances in the management of these patients have greatly reduced their morbidity and mortality. Special problems associated with SCI are presented in a later section.

Key Points: Pathogenesis

- Most UTIs are caused by bacteria, usually originating from the bowel and skin flora.
- Bacterial virulence factors, including adhesin, play a role in determining which bacteria invade and the extent of infection.
- Increased epithelial cell receptivity predisposes patients to recurrent UTIs and is a genotypic trait.
- Obstruction to urine flow is a key factor in increasing host susceptibility to UTIs.

Evaluation

Diagnosis of a UTI must involve a thorough history with a specific focus on signs and symptoms of the urinary complaints as well as investigating risk factors for infection. Physical exam, although necessary, is often unrevealing. Diagnosis of UTI is dependent on a properly collected urine sample. Additional testing is sometimes warranted, depending on the history.

Signs and Symptoms

Cystitis is typically associated with symptoms of dysuria, frequency, and/or urgency. Suprapubic pain, hematuria, and fever may also be present. Pyelonephritis is classically associated with fever, chills, flank pain, and costovertebral-angle tenderness. Nausea, vomiting, and malaise may be present. Urinary symptoms may or may not be present. Complicated UTIs can occur with other signs and symptoms. If patients complain of pneumaturia or fecaluria, a vesicoenteric or vesicovaginal fistula should be suspected. Renal or perirenal abscess may cause indolent fever and flank mass and tenderness. Patients with indwelling catheters often have asymptomatic bacteriuria, but fever associated with bacteremia may occur rapidly and become life threatening. Diagnosing a UTI in the geriatric population presents unique challenges (see the section on UTIs in the elderly).

In addition to focusing on presenting symptoms, other relevant information that must be ascertained includes recent infections (urologic and nonurologic) and/or antibiotic use, significant comorbidities that may predispose to infections, recent hospitalizations, presence of pediatric voiding dysfunction, sexual and reproductive history, known urologic anatomic abnormalities, prior surgery of the urinary tract, reproductive organs or spine, family history, and current medications (Box 55.3).

Box 55.3

Important Information in Evaluation of Urinary Tract Infection

- Recent infections/antibiotic use
- Recent hospitalizations
- Comorbidities
- History of pediatric voiding dysfunction
- Sexual and reproductive history
- Anatomic urologic abnormalities
- Prior surgery of genitourinary tract, reproductive organs, spine
- Family history
- Current medications

In the differential diagnosis of UTIs clinicians should consider voiding dysfunction that is not secondary to bacterial factors and will not improve with antibiotics targeted at a UTI (see chapters on interstitial cystitis/painful bladder syndrome, hematuria evaluation, STDs, VUR). For example, the symptoms associated with painful bladder syndrome may mimic a UTI, and, unfortunately, many patients who suffer from this syndrome are often treated with many courses of antibiotics despite the absence of documented positive cultures.

Furthermore, vaginitis is characterized by irritative voiding associated with vaginal irritation and is subacute in onset. A history of vaginal discharge or odor and multiple or new sexual partners is common. Frequency, urgency, hematuria, and suprapubic pain are not present. Physical examination reveals a vaginal discharge, and examination of vaginal fluid demonstrates inflammatory cells. Differential diagnosis includes herpes simplex virus, gonorrhea, *Chlamydia,* trichomoniasis, yeast, and bacterial vaginosis.

Last, urethritis causes dysuria that is usually subacute in onset and is associated with a history of discharge and new or multiple sexual partners. Frequency and urgency of urination may be present but are less pronounced than in patients with cystitis, and fever and chills are absent. Urethral discharge with inflammatory cells or initial pyuria in the male is characteristic. The common causes of urethritis include *Neisseria gonorrhoeae, Chlamydia,* herpes simplex virus, and trichomoniasis. Appropriate cultures and immunologic tests are indicated. Urethral injury associated with sexual intercourse, chemical irritants, or allergy may also cause dysuria. A history of trauma or exposure to irritants and a lack of discharge or pyuria are characteristic.

As a general rule, **painless gross hematuria, or microhematuria in the**

absence of a positive culture, should always raise the suspicion for urologic malignancy, and a hematuria evaluation must be initiated.

Physical examination should focus on the abdominal and pelvic regions. On examination of the suprapubic area, bladder distention may be palpated, often an indicator of an elevated postvoid residual. The presence or absence of costovertebral-angle tenderness should be assessed, particularly if the suspicion for pyelonephritis is high. During pelvic examination in a woman the presence of vaginal discharge should be noted. Inspection and palpation of the urethral area may identify the presence of a urethral diverticulum or Skene gland infection. If either of these are present, a cystic-appearing structure may be palpable or visualized. Fluid may be expressed on palpation of the area and tenderness may be elicited when palpating the cystic structure directly. In postmenopausal women careful attention should be focused on assessing the quality of the vaginal epithelium, specifically noting the degree of vaginal atrophy; atrophic vaginal tissue is an indicator of a hypoestrogenic state, which is a known risk factor for the development of UTIs. Pelvic organ prolapse may be identified as well; prolapse can contribute to incomplete emptying, which can be associated with a UTI. In men a rectal exam should be performed to assess the prostate. A focused neurologic exam on the pelvic area should be performed to assess whether sensation is intact.

Diagnosis by Urine Testing

Urine Collection

The diagnosis of a UTI is dependent on obtaining a properly collected urine sample with subsequent analysis of urine (urinalysis) and urine culture. Diagnostic accuracy and decreased rates of false-positive urinalysis and culture can be improved by reducing bacterial contamination during collection. Although studies have not demonstrated a clear benefit to cleansing the meatus before giving a midstream voided sample, it is a commonly accepted practice that is endorsed universally.

Before sample collection in circumcised men, the glans should be cleansed with a 2% castile soap towelette. For those uncircumcised, the foreskin should be retracted and the glans cleansed with the towelette before specimen collection. A midstream specimen should be obtained by collecting it in a sterile cup.

In women, contamination of a midstream urine specimen with introital bacteria and WBCs is common, particularly when the woman has difficulty maintaining separation of the labia. Women should therefore be instructed to spread the labia, wash and cleanse the periurethral area with a 2% castile soap towelette, and then collect a midstream urine specimen. The voided specimen is contaminated if it shows evidence of vaginal epithelial cells and lactobacilli on urinalysis. **Increased BMI, significant vaginal atrophy, decreased manual dexterity, and the inability to bear weight are factors that contribute to difficulty obtaining an adequate clean-catch midstream sample in women. The presence of an intravaginal pessary also increases the likelihood of obtaining a contaminated sample; if a woman has an indwelling pessary, analysis of a catheterized sample is preferable** (Box 55.4).

Box 55.4

Factors That Affect Ability to Provide Adequate Midstream Clean-Catch Sample

- Increased body mass index
- Vaginal atrophy
- Poor manual dexterity
- Inability to bear weight
- Intravaginal pessary
- Nonsterile collection receptacle

The collection receptacle also can affect the reliability of the sample. In some cases, voided urine samples, not collected via a midstream clean-catch sample, are collected from a bedpan or a nonsterile paper cup, rather than a sterile cup. This may occur in an emergency room setting or when a urine sample is requested during a well visit with a general practitioner or gynecologist. Analysis of these samples should be disregarded, but unfortunately patients are often treated based on abnormal findings in such erroneous samples, irrespective of symptoms. **If a patient has an indwelling Foley catheter and there is suspicion of a UTI, the catheter should be removed and a new catheter should be placed under sterile conditions to obtain a sample that reflects microbes in the urine, as opposed to microbes that may be colonizing the catheter or drainage bag**. Likewise, samples should not be taken from an ostomy appliance; rather they should be obtained via intubation of the stoma.

Catheterization with collection of a mid-catheterized specimen is more accurate than a voided specimen; however, because of its invasive nature it is only used in certain circumstances. Situations in which a catheterized sample should be considered include when the voided sample shows clear evidence of contamination (i.e., many squamous epithelial cells), a patient has a pessary, the patient is unable to provide an adequate clean-catch sample, or the patient cannot provide any sample at all. Although time intensive, the risk of iatrogenic infection is low and catheterization is critical to obtain the best quality samples, particularly if the symptoms of a UTI are equivocal. Indeed, a recent study evaluating the utility of catheterized samples in patients with symptoms not strongly suggestive of a UTI revealed obtaining a catheterized sample decreased the percent of patients who would have been treated with an antibiotic based on a positive voided sample by slightly more than 50% (Aisen et al., 2018).

Suprapubic aspiration is highly accurate, but because it is associated with some morbidity, there is limited clinical usefulness except for a patient who cannot urinate on command, such as patients with SCI. However, even in those populations, catheterized samples are preferred over suprapubic aspiration. A single aspirated specimen reveals the bacteriologic status of the bladder urine without introducing urethral bacteria.

Much of the evidence surrounding the efficacy of suprapubic aspiration for urine specimen collection comes from the pediatric literature regarding the diagnosis of a UTI in infants and young children. In 1999 the American Academy of Pediatrics published their Practice Parameter; in this guideline, they recommended that if an infant were ill enough to begin empiric antibiotic treatment, it was strongly recommended that a urine culture be obtained via suprapubic aspiration or catheterization. Given the high false-positive rate of urine culture obtained by bag collection, the Academy advised that suprapubic aspiration of urine for culture was the “gold standard.” Similar practice principles were set forth in the WHO guidelines for obtaining urine specimens in children (Long and Vince, 2007). These conclusions regarding the relative value of suprapubic aspiration may be extrapolated to the management of UTIs in adults, particularly in patients who cannot provide a midstream specimen nor are readily straight catheterized.

Further studies regarding the relative value of suprapubic aspirate specimens were done with the characterization of the urinary microbiome. In one of these early DNA sequencing studies by Wolfe et al. (2012), the goal was to obtain urine from the female urinary bladder in subjects without a known UTI that was not contaminated by any other sources (such as the vagina, gut, or skin) (Wolfe et al., 2012). To control for possible contamination, samples obtained by suprapubic aspiration were compared with control swabs of the sample site, samples from suprapubic needles that punctured the skin but did not penetrate the bladder, clean-catch midstream samples, and those specimens obtained by urethral catheterization. The microbiota obtained from suprapubic aspirate closely resembled that obtained by transurethral catheterization; in contrast, voided specimens contained organisms that more closely resembled vaginal swabs. This work not only established the presence of nonpathogenic bacteria in urine as part of the microbiome but also found that transurethral catheterization was akin to suprapubic aspirates in studying bladder microbiota. Because of this latter finding, suprapubic aspiration remains a viable option for the acquisition of "non-contaminated" urine samples, although the provider should assess individual patient circumstances to determine if this approach is to be used instead of straight catheterization.

Key Issues in Analysis of Urine Samples.

Certain components of a urine sample are highly suggestive of a UTI. Leukocyte esterase is produced by the breakdown of WBCs in the urine. Its presence is an indication of pyuria, but not bacteria specifically. As mentioned previously, the presence of WBCs and therefore leukocyte esterase is not uncommon in women with vaginal contamination. Nitrites are present when bacteria reduce dietary nitrates, via bacterial nitrate reductase activity. Not all bacteria produce nitrites, though, so the absence of nitrites does not mean bacteria are not present. **All Enterobacteriaceae produce nitrites, including *E. coli, Klebsiella, Enterobacter, Proteus, Citrobacter, Morganella,* and *Salmonella* spp. Non–nitrite-producing bacteria include all gram positives and Pseudomonads (e.g., Pseudomonas and Acinetobacter).** In addition, patients who adhere to low-nitrate diets may have false-negative results. The presence of nitrites has a high specificity but much lower sensitivity. The presence of leukocyte esterase and nitrites is more reliable when bacterial counts are more than 100,000 colony-forming units (CFUs) per milliliter. Cloudy urine may occur because of pyuria but it can also occur because of precipitated phosphate crystals in alkaline or concentrated urine.

Ideally a sample is analyzed in proximity to the time at which it was received. If a sample is left standing too long, it may become alkaline and subsequently may contain bacteria or lysed red cells. If the sample will not be analyzed within a few hours, it must be refrigerated, especially if not in a specimen cup that contains preservatives. Hydration can also dilute the concentration of certain constituents.

Urine Dipsticks.

Dipsticks, or chemically impregnated reagent strips, are often used in urgicares or medical clinics, or by patients at home when they develop symptoms of a UTI. **Although dipsticks are most helpful in ruling out a UTI, each parameter has false positives and negatives, which make it less reliable in determining whether a patient has a UTI.** However, in a patient who has symptoms strongly suggestive of a UTI, a positive dipstick can be helpful in determining whether to initiate antibiotics. A positive nitrite is the independent variable most likely to rule in a UTI, when analyzed in conjunction with symptoms (Meister et al., 2013). Analysis of several of the components of a dipstick increases the diagnostic abilities compared with just one component. **Positive nitrites or positive leukocyte esterase and blood on a dipstick most accurately diagnose a UTI** (Little et al., 2009; Marques et al., 2017).

However, the borderline sensitivity of dipsticks, especially among patients with less characteristic symptoms of UTIs, does not allow these inexpensive tests to replace careful microscopic urinalysis in symptomatic patients (Semeniuk and Church, 1999). In addition, results of a dipstick can be inaccurate if the test strips are expired or improperly stored. Some of the dipstick reagents, like nitrites, are sensitive to air exposure, so if a container of strips is not closed as soon as one is used, the other strips are more likely to give false-positive results in the future. The leukocyte reaction takes up to 5 minutes to occur, so if a strip is not observed for the appropriate duration, a patient may display a false-negative result.

Urinalysis.

Automated urinalysis allows for more sensitive detection of hematuria and bacteria in the urine as compared with dipsticks. Preferred collection tubes for urinalysis are those that have non-mercuric preservatives, such as a combination of chlorhexidine, ethylparaben, and sodium propionate. Such preservatives ensure the quality of the sample for up to 72 hours without refrigeration, therefore preventing bacterial overgrowth. Approximately 6 to 8 mL of urine is centrifuged at 1800 to 2000 RPM for 4 minutes, then examined. Microscopic analysis reports on the number of RBCs, WBCs, squamous epithelial cells, bacteria, crystals, and casts. The number of squamous cells is an indicator of the sample quality.

Abnormal results of any one urinary constituent is usually not pathognomonic of a UTI; thus several constituents must be evaluated together. **Multiple aspects of the urinalysis may indicate an acute inflammatory response, particularly pyuria (the presence of at least 5 to 10 leukocytes per high-power field) and hematuria. This information is valuable in conjunction with culture results given that bacteriuria may represent chronic colonization** versus acute infection. In addition, cultures typically require 48 to 72 hours to result; thus urinalysis provides for quick analysis. Ideally a sample is sent for analysis soon after the sample is given, with attention paid to proper sample collection. The strongest predictors of a UTI, in the correct clinical context, include moderate bacteriuria, moderate pyuria, and nitrites (Meister et al., 2013).

Pyuria can be found in several conditions other than UTIs, so the mere presence of WBCs in the urine is not diagnostic. Increasing numbers of WBCs present in a symptomatic patient, however, do support a UTI diagnosis. Indeed, it has been suggested that moderate pyuria, defined as WBC count greater than 50, in conjunction with symptoms suggestive of a UTI, justifies treatment with antibiotics (Meister et al., 2013). Other conditions known to cause pyuria include GU tuberculosis, urolithiasis, injury to the urothelium (including chlamydial urethritis), and interstitial nephritis. Depending on the level of hydration, the intensity of the tissue reaction producing the cells, and the method of urine collection, any number of WBCs can be seen in the microscopic sediment in the presence of an uninfected urinary tract. **The absence of pyuria should cause the diagnosis of UTI to be questioned until urine culture results are available. If a culture is positive yet no pyuria is demonstrated on urinalysis, clinicians should consider obtaining a catheterized sample.**

Bacteria may be present on initial urinalysis even though the final culture is negative, thus rendering the bacteria found on urinalysis a false-positive result. This is most likely to occur when vaginal bacteria, such as lactobacilli and corynebacteria, are present in a voided sample from a female patient.

Automated urinalysis can reliably rule out a UTI and preclude the need to order a urine culture (Kayalp et al., 2013). However, ruling in a UTI based on a urinalysis is not as straightforward, because urinalyses may have abnormal parameters even in healthy, asymptomatic women, using preferred collection techniques (Frazee et al., 2015). Thus **relying on results of urinalyses alone**

can lead to overdiagnosis of UTIs. It is critically important that results of urinalyses are interpreted in conjunction with the clinical presentation and eventually correlation with a urine culture.

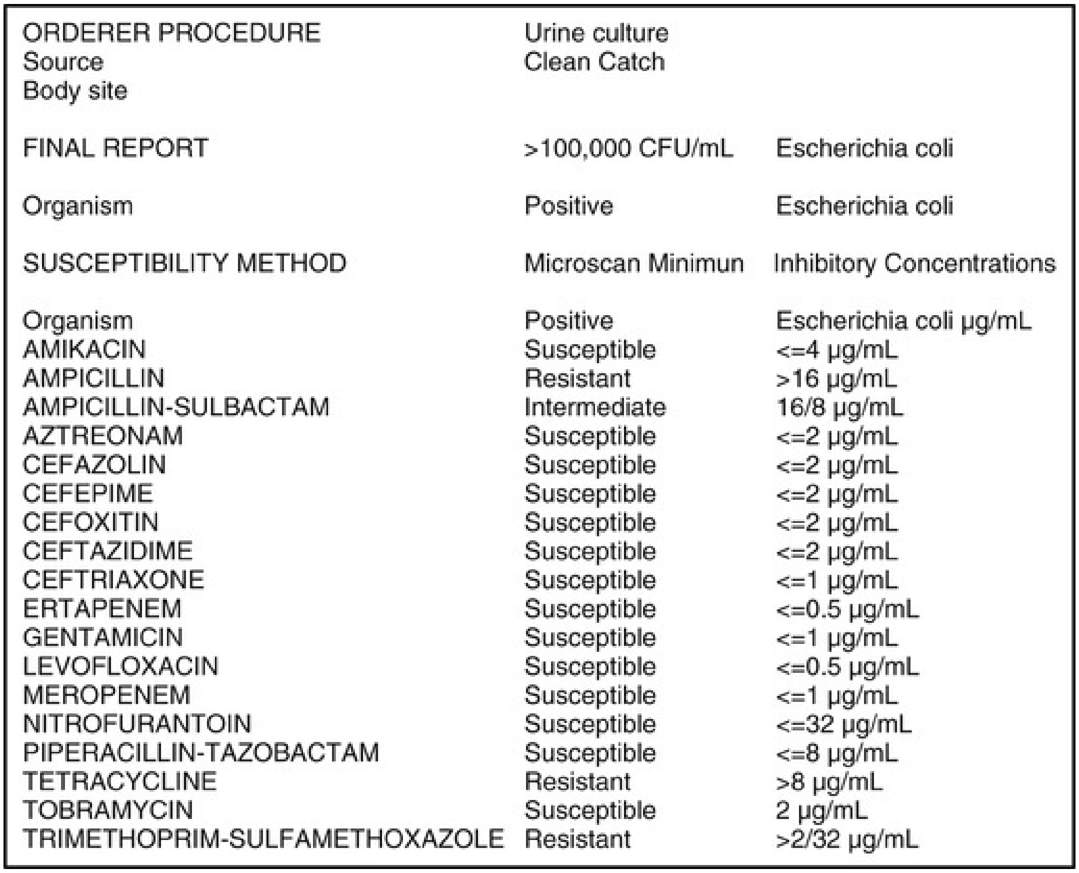
Urine Culture.

Standard urine culture is the gold standard for identifying the presence of bacteriuria, which supports a diagnosis of UTI in the symptomatic patient. The technique was originally described in the 1950s. Ideally, urine is collected via a midstream clean-catch sample or catheterized sample and is placed in a vacutainer tube that contains freeze-dried preservatives, which practically eliminate false-positive results. The sample is then placed on blood agar and MacConkey culture plates.

Historically, a colony count of at least 10^5 CFU/mL of urine was used to diagnose a UTI. Initially, this colony count confirmed a diagnosis of pyelonephritis (Kass, 1956) but has subsequently been employed to make a diagnosis of cystitis as well. However, many studies have demonstrated that women with dysuria may have lower bacterial colony counts. Indeed, 20% to 40% of women with symptomatic UTIs have bacteria counts of 10^2 to 10^4 CFU/mL of urine (Kraft and Stamey, 1977; Kunz et al., 1975; Stamey et al., 1965), probably because of the slow doubling time of bacteria in urine (every 30 to 45 minutes) combined with frequent bladder emptying (every 15 to 30 minutes) from irritation. **Thus, in dysuric patients, an appropriate threshold value for defining significant bacteriuria is 10^2 CFU/mL of a known pathogen** (Stamm and Hooton, 1993).

Urine culture results are reported as negative, commensal flora, or positive. Commensal flora includes coagulase-negative staphylococci, alpha and non-hemolytic streptococci, diphtheroids, non-pathogenic *Neisseria* spp., and yeasts. Results of positive urine cultures are reported with antibiotic sensitivities for each pathogen: S (sensitive), I (indeterminate), and R (resistant), with the minimum inhibitory concentration (MIC) following the sensitivities. **The MIC is the lowest concentration of an antibiotic that inhibits growth of an organism.** If an antibiotic is listed as sensitive, it suggests that growth of an organism is inhibited by the serum concentration of the medication that is achieved using the recommended dose. If listed as indeterminate, the antibiotic still may be effective in locations where the medication is physiologically concentrated or a higher-than-recommended dose can be used. Resistant organisms are those that are resistant to standard achievable serum drug levels

(Fig. 55.10). **Efficacy of the antimicrobial therapy is critically dependent on the antimicrobial levels in the urine and the duration that this level remains above the minimal inhibitory concentration of the infecting organism** (Hooton and Stamm, 1991). **Resolution of infection is closely associated with the susceptibility of the bacteria to the concentration of the antimicrobial agent achieved in the urine** (McCabe and Jackson, 1965; Stamey et al., 1965, 1974). The concentration of useful antimicrobial agents in the serum and urine of healthy adults is shown in eTable 55.1, which demonstrates that the **urinary levels are often several hundred times greater than the serum levels. Inhibitory concentrations in urine are achieved after oral administration of all commonly used antimicrobial agents, except for the macrolides (erythromycin).**



ORDERER PROCEDURE	Urine culture	
Source	Clean Catch	
Body site		
FINAL REPORT	>100,000 CFU/mL	Escherichia coli
Organism	Positive	Escherichia coli
SUSCEPTIBILITY METHOD	Microscan Minimun	Inhibitory Concentrations
Organism	Positive	Escherichia coli μg/mL
AMIKACIN	Susceptible	<=4 μg/mL
AMPICILLIN	Resistant	>16 μg/mL
AMPICILLIN-SULBACTAM	Intermediate	16/8 μg/mL
AZTREONAM	Susceptible	<=2 μg/mL
CEFAZOLIN	Susceptible	<=2 μg/mL
CEFEPIME	Susceptible	<=2 μg/mL
CEFOXITIN	Susceptible	<=2 μg/mL
CEFTAZIDIME	Susceptible	<=2 μg/mL
CEFTRIAXONE	Susceptible	<=1 μg/mL
ERTAPENEM	Susceptible	<=0.5 μg/mL
GENTAMICIN	Susceptible	<=1 μg/mL
LEVOFLOXACIN	Susceptible	<=0.5 μg/mL
MEROPENEM	Susceptible	<=1 μg/mL
NITROFURANTOIN	Susceptible	<=32 μg/mL
PIPERACILLIN-TAZOBACTAM	Susceptible	<=8 μg/mL
TETRACYCLINE	Resistant	>8 μg/mL
TOBRAMYCIN	Susceptible	2 μg/mL
TRIMETHOPRIM-SULFAMETHOXAZOLE	Resistant	>2/32 μg/mL

FIG. 55.10 Minimum inhibitory concentration for *E. coli* urinary tract infection, demonstrating sensitivity to most antibiotics except ampicillin, ampicillin-sulbactam, tetracycline, and trimethoprim-sulfamethoxazole.

eTABLE 55.1

Clinical Examples of Ureteral Catheterization Studies in Localizing the Site of Bacteriuria

SOURCE OF RENAL INFECTION	BLADDER INFECTION (BACTERIA/mL)	LEFT RENAL INFECTION (BACTERIA/mL)	RIGHT RENAL INFECTION (BACTERIA/mL)	BILATER (BACTERI
CB	$>10^5$	5000	$>10^5$	4000

RK$_4$	0	0	12,000	250

CB, Catheterized patient, cystoscopic specimen; *LK$_1$, LK$_2$, etc.,* serial cultures of urine from the left kidney; *RK$_1$, RK$_2$, etc.,* serial cultures of urine from the right kidney; *WB,* controlled, “wash bladder” specimen collected after copious irrigation of the bladder.

Data from Stamey T: *Pathogenesis and treatment of urinary tract infections*, Baltimore, 1980, Williams & Wilkins.

Factors other than the MIC should be taken into account when selecting an antibiotic, such as anatomic location of the infection and fluid type that is harboring infection (i.e., urine vs. blood). The lowest MIC is not always the most effective option. Route of administration should also be considered when determining which antibiotic to choose. This is particularly important in the outpatient setting when patients demonstrate the presence of multidrug-resistant organisms.

The specific pathogen identified in the culture is also a critical factor in evaluating the need to proceed with treatment, particularly if symptoms are equivocal. Although there is consensus regarding the benefit of treating a symptomatic patient who has gram-negative rods in the urine, the significance of gram-positive organisms in women is more controversial. In many cases a gram-positive organism may represent a periurethral contaminant. In a study comparing the presence of uropathogens in voided samples versus catheterized samples in symptomatic premenopausal women, the presence of *E. coli* in midstream samples had a high positive predictive value (93%) of bladder bacteriuria, even at low colony counts, whereas the presence of enterococci and group B streptococci were not predictive of bladder bacteriuria at any colony count (Hooton et al., 2013). In women who grew enterococci and/or group B streptococci in a voided sample, *E coli* grew from a catheterized sample in 61% of these subjects. The authors concluded that gram-positive organisms rarely cause acute cystitis in isolation.

In some cases, despite symptoms and a UA that are suggestive of a UTI, a standard urine culture may be negative. In this scenario a culture should be sent specifically looking for atypical organisms such as *Ureaplasma urealyticum* or *Mycoplasma hominis.*

Recently, more sensitive culture techniques have been described, known as the Expanded Quantitative Urine Culture (EQUC) (see the section on microbiome). Although the EQUC is not widely used yet, its ability to detect more organisms in the urine challenges traditional thinking about cutoff thresholds for the diagnosis of UTIs as well as the concept that polymicrobial presence should be discounted as a contaminant. Some have argued that the standard urine culture should no longer be considered the gold standard for detecting uropathogens (Price et al., 2018). **With more sophisticated techniques available to detect microbes, clinical judgment is paramount to prevent overtreatment of bacteriuria.**

Key Points: Evaluation

- Clinical presentation is critical in considering diagnosis; results of urine testing cannot be analyzed without knowledge of signs and symptoms.
- Urine must be collected in a manner that minimizes contamination.
- Formal urinalysis is preferred over dipstick testing.
- Urine culture results provide information regarding bacterial sensitivities.

Localization

Ureteral Catheterization

In cases of bacterial persistence it is useful to try to identify the source. Ureteral catheterization allows separation of not only bacterial persistence into upper and lower urinary tracts but also the infection between one kidney and the other, and even localization of infection to ectopic ureters or to nonrefluxing ureteral stumps (by using saline solution irrigation) (Stamey, 1980). Attempts to identify one or both kidneys as a source of infection are particularly important in patients with fever, flank pain, and/or costovertebral angle tenderness. This modality of diagnostics is also particularly important for the patient with renal transplant in determining if the native kidneys are harboring infection contributing to a UTI (see eTable 55.1).

Stone Cultures

It is clinically useful to culture stones removed from the urinary tract to identify the bacteria—and their sensitivities—that reside within their interstices. Urinary and stone cultures must be analyzed separately because results may be discordant. UTIs are the most common complication after stone removal procedures. Manipulation of infected stones, and possible release of endotoxins into the bloodstream, can lead to systemic inflammatory response syndrome (SIRS) or potentially fatal urosepsis. Studies have shown that stone cultures, rather than periprocedure urine cultures, are a better predictor of postoperative sepsis and SIRS (Korets et al., 2011; Mariappan et al., 2005).

Imaging

Imaging studies are not required in most cases of UTI because clinical and laboratory findings are sufficient for correct diagnosis, initiation of treatment, and adequate management of most patients. However, infections in most men, compromised hosts, febrile infections, signs or symptoms of urinary tract obstruction, failure to respond to appropriate therapy, and a pattern of recurrent infections suggesting bacterial persistence within the urinary tract warrant imaging for identification of underlying abnormalities that require modification of medical management or percutaneous or surgical intervention (Box 55.5).

Box 55.5

Indications for Radiologic Investigation in Acute Clinical Pyelonephritis

Potential ureteral obstruction (e.g., caused by stone, ureteral stricture, tumor)
History of calculi, especially infection (struvite) stones
Potential papillary necrosis (e.g., patients with sickle cell anemia, severe diabetes mellitus, analgesic abuse)
History of genitourinary surgery that predisposes to obstruction, such as ureteral reimplantation or ureteral diversion
Poor response to appropriate antimicrobial agents after 5 to 6 days of treatment
Diabetes mellitus
Polycystic kidneys in patients in dialysis or with severe renal insufficiency
Neuropathic bladder
Unusual infecting organisms, such as tuberculosis, fungus, or urea-splitting organisms (e.g., *Proteus*)

A UTI associated with possible urinary tract obstruction must be urgently evaluated. This refers to patients with calculi, especially infection (struvite) stones; ureteral tumors; ureteral strictures; congenital obstructions; or previous

GU surgery, such as ureteral reimplantation or urinary diversion procedures that may have caused obstruction. Patients with **diabetes mellitus** can develop special complications from UTIs; they may acquire emphysematous pyelonephritis or papillary necrosis. **Impacted necrotic papillae** may cause acute ureteral obstruction. Patients with **polycystic kidney disease who are on dialysis** are particularly prone to developing perinephric abscesses.

Urologic imaging is indicated in patients whose symptoms of acute clinical pyelonephritis persist after several days of appropriate antimicrobial therapy; they may manifest perinephric or renal abscesses. In addition, **patients with unusual organisms,** including urea-splitting organisms (e.g., *Proteus* species), should be examined for abnormalities within the urinary tract, such as obstructing stones, strictures, or fungus aggregates.

The second reason for radiologic evaluation is to diagnose a focus of bacterial persistence. **In patients whose bacteriuria fails to resolve after appropriate antimicrobial therapy or who have rapid recurrence of infection, abnormalities that allow bacterial persistence should be sought.** Although uncommon, it is important to identify causes of persistence because they may represent surgically correctable urologic abnormalities. Acquired or congenital urologic abnormalities that can cause unresolved or recurrent UTIs are listed in Box 55.6.

Box 55.6

Correctable Urologic Abnormalities That Cause Bacterial Persistence

- Infection stones
- Chronic bacterial prostatitis
- Unilateral infected atrophic kidneys
- Ureteral duplication and ectopic ureters
- Foreign bodies
- Urethral diverticula and infected periurethral glands
- Unilateral medullary sponge kidneys
- Nonrefluxing, normal-appearing, infected ureteral stumps after nephrectomy
- Infected urachal cysts

- Infected communicating cysts of the renal calyces
- Papillary necrosis
- Perivesical abscess with fistula to bladder

Ultrasonography

Renal and bladder ultrasound (RBUS) is an important imaging technique because it is noninvasive, easy and rapid to perform, and offers no radiation or contrast agent risk to the patient. Ultrasound is particularly useful in identifying calculi and hydronephrosis, pyonephrosis, and perirenal abscesses. Although with the known pitfalls of limited sensitivity, a single radiograph for calculi could accompany ultrasonography. Ultrasonography is also useful for diagnosing postvoid residual urine. A disadvantage is that the study is dependent on the interpretative and performance skills of the examiner. Furthermore, the study may be technically poor in patients who are obese or have other anatomic challenges, or who have dressings, drainage tubes, or open wounds overlying the area of interest. **The sensitivity of ultrasound for demonstrating renal parenchymal abnormalities in acute pyelonephritis is lower than that of CT and MRI; it is lower than that of CT for detecting small renal stones and most ureteral stones and is less accurate than CT in detecting ureteral obstruction.**

Computed Tomography and Magnetic Resonance Imaging

The radiologic modalities that offer the best anatomic detail for evaluation of UTI are CT and MRI. These studies are more sensitive than excretory urography or ultrasonography in the diagnosis of acute focal bacterial nephritis, renal and perirenal abscesses, and radiolucent calculi (Kuhn and Berger, 1981; Mauro et al., 1982; Soler et al., 1997; Soulen et al., 1989; Wadsworth et al., 1982). When used to localize renal and perirenal abscesses, CT improves the approach to surgical drainage and permits percutaneous approaches. MRI has not supplanted CT in the evaluation of renal inflammation, but it has provided some advantages in delineating extrarenal extension of inflammation. Pelvic MRI is the most useful imaging modality for detecting a urethral diverticulum.

Voiding Cystourethrogram

The voiding cystourethrogram is an important examination in assessing VUR. In women with a history of febrile UTIs, known VUR as a child, or recurrent pyelonephritis as an adult, a voiding cystourethrogram (VCUG) should be performed. VCUG should also be considered in patients with a history of recurrent UTIs and hydronephrosis detected on upper tract imaging. Historically VCUG with a double-balloon catheter was recommended if there was suspicion of a urethral diverticulum; however, the current standard of care used is pelvic MRI.

Radionuclide Studies

Although such radiologic evaluations are rarely employed in current practice, hippuran I-131 and technetium-99m (^{99m}Tc) glucoheptonate and dimercaptosuccinic acid scans may be used to detect focal parenchymal damage, renal function impairment, and decreased renal perfusion in acute renal infections (McAfee, 1979). Gallium-67 scanning has also been reported to be useful in the diagnosis of pyelonephritis and renal abscess; it is uncommonly required and may be positive even with in noninfectious entities. Indium-111–labeled WBC studies may have limited efficacy in establishing the presence of an inflammatory focus, particularly when the patient's clinical presentation does not suggest an infectious process.

Microbiome

Contrary to traditional thought, urine is not sterile. In recent years, 16S ribosomal RNA sequencing analysis has been used to help determine that many bacterial species inhabit the urinary tract of healthy men and women who do not have symptoms of a UTI (Lewis et al., 2013; Nelson et al., 2010; Wolfe et al., 2012). Standard culture techniques readily identify fast-growing bacteria that thrive in an oxygen-rich environment. However, many bacteria require special nutrients or are anaerobic and thus will not grow in standard culture preparations. This initial work involving the urinary microbiome has since revolutionized our thought process when it comes to identifying bacteria in the urinary tract. Although bacteria in the urine were traditionally thought of as categorically pathological, it is now established that bacteria are present in the urine of symptomatic as well as asymptomatic men and women.

Once the female urinary microbiome was identified, researchers started investigating whether modifying standard culture techniques would enable detection of bacteria that previously would have been missed. Indeed, using an expanded quantitative urine culture (EQUC) protocol, many bacteria were identified that would have been missed using standard culture preparations (Hilt et al., 2014). The EQUC specifically analyzed a larger volume of urine, which was subject to different atmospheric conditions and longer incubation times. Hilt et al. then compared standard culture protocols to the EQUC protocol in 65 samples from patients with or without overactive bladder symptoms. They found that 52/65 samples grew bacteria in the EQUC protocol group, yet 48 of these 52 were negative in standard culture cohort. Beyond typical bacteria often cultured in urine, 35 different genera and 85 different species were identified. This discovery further supported the notion that the female urinary microbiome exists and contains many different nonpathogenic microbiota (Table 55.2).

TABLE 55.2

List of Bacterial Species Cultured in Different Conditions

ORGANISM	AEROBIC 35°	AEROBIC 30°	CO_2 35°	ANAEROBIC 35°	CAMPY (6% O_2, 10% CO_2) 35°

The “+” symbol designates the environmental conditions from which the organism was isolated and identified. The “HD” symbol indicates that only high-dilution (1 µL) urine was plated for that condition and that no growth was observed. A blank space designates no growth in that condition for that particular organism using a low-dilution (100 µL) inoculum. The (#) next to the organism name designates the number of times the organism has been isolated.

Data from Hilt EE, McKinley K, Pearce MM, et al.: Urine is not sterile: use of enhanced urine culture techniques to detect resident bacterial flora in the adult female bladder. *J Clin Microbiol.* 52(3):871–876, 2014.

Now that we are aware of the existence of the female urinary microbiome,

we face the "challenge of interpretation": we must determine when and how to treat bacteria in the urinary tract with the acknowledgment that we will never, nor should we strive to, eradicate all bacteria (Brubaker and Wolfe, 2017). Indeed, many bacteria within the microbiome are considered protective (Brubaker et al., 2014; Pearce et al., 2014). Ongoing research seeks to determine if disruptions in the established microbiota are seen in certain forms of lower urinary tract pathology, focusing particularly on determining whether the microbiome differs in women with conditions such as urge incontinence or painful bladder syndrome (Nickel et al., 2016; Thomas-White et al., 2016).

In line with this understanding of a dynamic urinary microbiome that affects bladder physiology, emerging scientific theories continue to develop and explore the concept that urine has a role beyond purely functioning as a vehicle for excretory waste. First, the Urinology Think Tank, a group supported by the National Institute of Diabetes and Digestive and Kidney Disease, is investigating the notion that properties intrinsic to urine, including the microbiotia, exfoliated cells, exosomes, pH, metabolites, protein, and specific gravity, may interact with the urothelium to influence bladder function and homeostasis (Urinology Think Tank Writing, 2018). Furthermore, emerging basic science work continues to explore the possibility that the constituents of urine, including donor-derived urine stem cells, can be used for human cell therapy and autologous repair (Pavathuparambil Abdul Manaph et al., 2018).

Key Points: Microbiome

- Urine is not sterile.
- The female urinary microbiome has been identified using RNA sequencing techniques, and knowledge of these microbiota should inform UTI management and interpretation of novel culture techniques such as the EQUC protocol.

Asymptomatic Bacteriuria

The management of asymptomatic bacteriuria has evolved with time, even before the identification of the urinary microbiome, which essentially renders the term “asymptomatic bacteriuria” obsolete. Nonetheless, for the purposes of this chapter, we will continue to use this term and review its significance.

The term *asymptomatic bacteriuria* is appropriately used when a person has no signs or symptoms of a UTI, yet bacteria are identified in a noncontaminated urine sample. In women, the term *asymptomatic bacteriuria* is used when the same bacteria is identified in quantitative counts of greater than or equal to 100,000 CFUs in two consecutive voided samples that are obtained in a fashion that minimizes contamination. In men, only one clean-catch voided sample that identifies one bacterial species in quantitative counts greater than or equal to 100,000 CFUs is necessary to use the term *asymptomatic bacteriuria* appropriately. Alternatively, in men or women, one catheterized sample that identifies a single bacterial species in a quantitative count of greater than or equal to 100 can make the diagnosis of asymptomatic bacteriuria (Nicolle, et al., 2005; Box 55.7).

Box 55.7

Diagnosis of Asymptomatic Bacteriuria

- Lack of signs and symptoms of UTI
- Diagnosis based on urine specimen collected in a manner that minimizes contamination
- For asymptomatic women: 2 consecutive voided urine specimens with isolation of same bacterial strain in quantitative counts ≥100,000 CFUs/mL
- For asymptomatic men: single voided urine specimen with one bacterial species isolated in quantitative count ≥100,000 CFUs/mL
- For women or men: single catheterized urine specimen with one bacterial species isolated quantitative count ≥100 CFUs/mL

CFUs, Colony-forming units; *UTI*, urinary tract infection.

Data from Nicolle LE, Bradley S, Colgan R, et al.: Infectious Diseases Society of America guidelines for the diagnosis and treatment of asymptomatic bacteriuria in adults. *Clin Infect Dis* 40(5):643–654, 2005. Based on ISDA guidelines.

The prevalence of asymptomatic bacteriuria varies based on age, sex, and comorbid conditions. First, the prevalence of asymptomatic bacteriuria increases with age: it has been identified in approximately 1% of school-age girls but is present in greater than 20% of healthy women older than 80 years of age who are community dwellers (Nicolle, 2003). It also correlates with sexual activity; in fact population studies have identified a prevalence in premenopausal, married women of 4.6%, whereas in age-matched nuns the prevalence is only 0.7% (Kunin and McCormack, 1968). Menopause is also a risk factor for asymptomatic bacteriuria with a prevalence estimated as 1% to 5% in healthy premenopausal women and 2.8% to 8.6% in postmenopausal women between the ages of 50 and 70 (Nicolle, 2003). In younger men, asymptomatic bacteriuria is uncommon (Lipsky, 1989). As men age, the prevalence increases; in elderly (>75 years old) community dwellers it has been quoted as 6% to 15% (Nicolle, 2003). The overall prevalence is increased in both sexes living in long-term care facilities: it has been reported in 25% to 50% of women and 15% to 40% of men in facilities (Nicolle, 1997). Asymptomatic bacteriuria is more common in female patients with diabetes as compared with males (9%–27% vs. 0.7%–11%) (Zhanel et al., 1991a,b). The presence of asymptomatic bacteriuria is also strongly associated with duration of disease as well as comorbidities associated with poorly controlled diabetes (Zhanel et al., 1995). In patients with SCI who perform clean intermittent catheterization (CIC), the prevalence is 23% to 89% (Bakke and Digranes, 1991). Finally, the prevalence in patients with long-term indwelling catheters is 100% (Warren et al., 1982). **As demonstrated by all of these statistics, risk factors for asymptomatic bacteriuria include advanced age, female gender, institutionalization, comorbid conditions such as diabetes, and catheterization/presence of an indwelling Foley catheter** (Colgan et al., 2006; Table 55.3).

TABLE 55.3

Prevalence of Asymptomatic Bacteriuria in Selected Populations

POPULATION	PREVALENCE (%)	REFERENCE
Healthy, premenopausal women	1.0–5.0	Nicolle, 2003
Pregnant women	1.9–9.5	Nicolle, 2003
Postmenopausal women aged 50–70 years	2.8–8.6	Nicolle, 2003
Patients with diabetes		
Women	9.0–27	Zhanel et al., 1991a
Men	0.7–11	Zhanel et al., 1991a
Elderly persons in the community		
Women	10.8–16	Nicolle, 2003
Men	3.6–19	Nicolle, 2003
Elderly persons in a long-term care facility		
Women	25–50	Nicolle, 1997
Men	14–50	Nicolle, 1997
Patients with spinal cord injuries		
Intermittent catheter use	23–89	Bakke and Digranes, 1991
Sphincterotomy and condom catheter in place	57	Waites et al., 1993b
Patients undergoing hemodialysis	28	Chaudhry, 1993
Patients with indwelling catheter use		
Short-term	9–23	Stamm, 1991
Long-term	100	Warren, 1982

Data from Nicolle LE, Bradley S, Colgan R, et al.: Infectious Diseases Society of America guidelines for the diagnosis and treatment of asymptomatic bacteriuria in adults. *Clin Infect Dis* 40:643–654, 2005.

In older women living in the community, *E. coli* is the predominant pathogen isolated in asymptomatic women; it was found in 51.4% of samples in one study. Other species of bacteria were found in fewer than 10% of samples and included *Klebsiella pneumoniae*, *Proteus mirabilis*, and *Enterococcus faecalis* (Linhares et al., 2013). The *E. coli* strains identified in women with asymptomatic bacteriuria have less virulence factors than other strains that cause symptomatic urinary infections (Svanborg, 1997). Molecular studies have shown that some *E. coli* strains are actually commensal strains, whereas others may have initially been virulent but transitioned into commensal strains (Klemm et al., 2007; Zdziarski et al., 2008). In men, gram-negative bacilli, enterococci, and coagulase-negative staphylococci are common pathogens identified in the urine (Lipsky et al., 1984; Mims et al., 1990). The bacterial isolates vary in institutionalized patients or those with indwelling catheters, as compared with community dwellers. In this former population, polymicrobial bacteriuria is frequent; common bacteria found in these populations include *Pseudomonas aeruginosa*, *Morganella morganii*, and *Providencia stuartii* (Nicolle, 1993, Nicolle et al., 2005).

Historically there was concern that untreated asymptomatic bacteriuria may be a risk factor for recurrent UTIs and long-term sequelae such as hypertension, renal insufficiency, or development of urinary tract cancer. However, studies have shown that this is not the case (Bengtsson et al., 1998; Tencer, 1988). **On the contrary, more recent work establishes that treating asymptomatic bacteriuria in all groups is potentially deleterious** (Cai et al., 2012, 2015). Indeed, treatment can lead to an increased risk of subsequent symptomatic UTIs, increased costs associated with treatment of bacteriuria, and potential adverse effects of antibiotics.

To promote a universal approach to the diagnosis and management of asymptomatic bacteriuria in adult populations greater than 18 years old, the **Infectious Disease Society of America (IDSA) published guidelines in 2005 (that are endorsed by the AUA)** (Nicolle et al., 2005). **These guidelines clearly stipulate that, in the majority of patients, asymptomatic bacteriuria should not be treated. Specifically, it should not be treated in the following populations: premenopausal, non-pregnant women; women with diabetes; older community dwellers; elderly institutionalized patients; patients with SCI; and patients with indwelling catheters. On the contrary, it should always be treated in pregnant women and in patients who are undergoing procedures in which transmucosal bleeding is anticipated.** Pyuria, which in isolation often triggers many practitioners to recommend antimicrobial therapy, is not an indication to treat even if it is found in conjunction with asymptomatic bacteriuria. No recommendation was made for whether to treat asymptomatic bacteriuria in renal transplant patients or other immunocompromised hosts (Box 55.8). The IDSA published an update to this guideline in 2019. This update included populations not addressed in the 2005 guideline, specifically children and patients with solid organ transplants or neutropenia (Nicolle et al., 2019).

Box 55.8

Treat or Not Treat Asymptomatic Bacteriuria

Do Not Treat: premenopausal, non-pregnant women, women with diabetes, older community dwellers, elderly institutionalized patients, patients with spinal cord injury, patients with indwelling catheters, pyuria with asymptomatic bacteriuria

Treat: pregnant women, patients undergoing procedures in which transmucosal bleeding is anticipated

---

Data from Nicolle LE, Bradley S, Colgan R, et al.: Infectious Diseases Society of America guidelines for the diagnosis and treatment of asymptomatic bacteriuria in adults. *Clin Infect Dis* 40(5):643–654, 2005. Based on ISDA guidelines.

The US Preventive Services Task Force (USPSTF) concurred with the IDSA, and in 2008 published a statement urging people not to indiscriminately screen for asymptomatic bacteriuria (Lin et al., 2008). This task force looked at several different types of studies that included pregnant and non-pregnant women as well as men. The Taskforce concluded that women who are pregnant are the only group who should be screened for asymptomatic bacteriuria.

Likewise, a Cochrane review published in 2015 also concluded that treatment of asymptomatic bacteriuria is not recommended (Zalmanovici Trestioreanu et al., 2015). This review included nine randomized or “quasi” randomized controlled studies, which included a total of 1614 subjects. Studies were not included in this review if they contained any of the following subjects: pregnant women, subjects who either had indwelling catheters or performed CIC, subjects who had indwelling stents or nephrostomy tubes, transplant recipients, subjects who had bacteriuria related to recent urologic procedures, patients with SCI, or hospitalized patients. The review found that symptomatic UTI, complications, and death were similar between the subjects who were treated with antibiotics and those who were not. Although bacteriuria was eradicated more often in those treated, more adverse effects were also noted in this population. No decline in renal function was identified in those not treated.

One of the studies included in the Cochrane review looked at young sexually active women who were seen in a sexually transmitted disease clinic in Italy for recurrent UTIs between 2005 and 2009 (Cai et al., 2012). Subjects were included in the study if they had at least one symptomatic UTI in the 12 months before enrollment and had documented asymptomatic bacteriuria at the onset of the study. The participants were then randomized into two groups: in group A, asymptomatic bacteriuria was observed, whereas in group B, it was treated. At periodic intervals (3, 6, 12 months), their urine samples were analyzed for the presence of bacteriuria. A total of 673 women between the ages of 18 and 40 were studied. The data showed that those in group B had a higher rate of symptomatic UTI over 1 year, as compared with the untreated women in group A. Multivariate analysis showed that antibiotic use was an independent risk factor ($P < 0.001$; hazard ratio, 3.09; 95% CI) for the development of a symptomatic UTI. The majority of subjects who had not had a symptomatic UTI did have asymptomatic *E. faecalis* present in their urine with late follow-up. The investigators concluded that treatment of asymptomatic bacteriuria may remove the protective benefit of an asymptomatic strain.

With extended follow-up of this study population (albeit a smaller total population of 550 subjects because of dropout during extended follow-up), the difference in recurrence rates for symptomatic UTIs was statistically significant ($P < 0.001$) at a mean of 38.8 months (Cai et al., 2015). In group A, 97 (37.7%) subjects recurred, while in group B, 204 (69.6%) recurred. In addition to demonstrating higher recurrence rates in the treated group, the *E. coli* isolated in group B showed higher resistance to several antibiotics, including amoxicillin-clavulanic acid, TMP-SMX, and ciprofloxacin as compared with *E. coli* isolates from group A. The increased resistance rates were not seen until at least 2 years of follow-up. The authors concluded that use of antibiotics in women with asymptomatic bacteriuria and a history of recurrent UTIs must be discouraged. These findings overall further corroborate the IDSA guidelines.

Despite the extensive data available that argue against treating asymptomatic bacteriuria, unfortunately inappropriate antibiotic treatment is still a widespread problem. Ferroni et al. cite several translational barriers to the adoption of IDSA principles among all practitioners; these include a lack of awareness, confusion regarding the guidelines, and continued fear about adverse outcomes associated with not prescribing an antibiotic (Ferroni and Taylor, 2015; James et al., 1998; Wolfe et al., 2004). Indeed a study by Ditkoff et al. (2018) showed that more than 50% of practitioners from a variety of specialties including family practice, internal medicine, gynecology, urology, and emergency medicine were not aware of IDSA guidelines for management of asymptomatic bacteriuria or acute cystitis. Cumulatively, these data suggest that there is more work to be done to normalize the standards of care, because the sequelae of in appropriate antibiotic use remains a growing concern from the standpoint of individual patient care and from a public health perspective.

Interestingly, although many providers ignore the recommendations not to treat, some are actually using asymptomatic bacteriuria as a prophylactic strategy against the development of UTIs (Nicolle, 2015). Known as bacterial interference, this therapy involves establishing the presence of avirulent bacteria in the urinary tract to essentially "block" virulent organisms from invading the urinary tract. Preliminary studies have not been conclusive in terms of efficacy and study design and interpretation of results have been complicated. Nonetheless, this concept of bacterial interference merits further investigation in the future.

The management of asymptomatic bacteriuria before nonurologic surgery is another topic that lacks a universal approach. Perhaps this question has best been studied as it pertains to the management of asymptomatic bacteriuria before joint replacement surgery. Recent data challenge the traditional dogma that asymptomatic bacteriuria should be treated before joint surgery to reduce the risk of developing a septic joint. One multicenter, multinational study by Sousa et al. (2014) specifically looked at the incidence of postoperative joint infections in 2497 patients with and without asymptomatic bacteriuria who underwent knee or hip arthroplasties. A total of 12.1% (n = 303) of these patients had asymptomatic bacteriuria preoperatively, and 154 patients in this cohort were pretreated before surgery. The postoperative joint infection rate within the entire population was 1.7%. In patients with asymptomatic bacteriuria, the joint infection rate was significantly higher than in the group who were not bacteriuric (4.3% vs. 1.4%; OR 3.23; 95% CI). However, treatment of asymptomatic bacteriuria did not significantly affect the development of postoperative joint infections. In those treated, which was a decision made by the individual physician and was not randomized, the rate of infections was 3.9%, whereas in the untreated group it was 4.7%, which was not a statistically significant difference. Interestingly, although the bacteriuric patients had a higher incidence of gram-negative prosthetic infections, the organism cultured from the urine was not the same as the organism cultured from the joint. The authors concluded that the presence of asymptomatic bacteriuria is a surrogate marker for increased risk of infection overall, but preoperative treatment of the bacteriuria did not modulate the likelihood of remaining infection free in the joint. Therefore **treatment of asymptomatic bacteriuria before orthopedic surgery is not recommended.**

A more recent study by Lamb et al. (2017) concluded that obtaining preoperative urine cultures before joint replacement surgery is not necessary because the presence of asymptomatic bacteriuria does not correlate with the incidence of prosthetic joint infections. They compared the incidence of joint infections during a period when preoperative urine cultures were routinely obtained to the incidence after the adoption of a policy that eliminated urine cultures from preoperative order sets. Although the joint infection rate was no different, the financial impact to the health care system was drastic: without the cost of processing urine cultures the savings were approximately $20,000 per year. This study thus introduces another added consideration, in the form of cost savings, when advocating for restraint in the screening and treatment of asymptomatic bacteriuria.

Key Points: Asymptomatic Bacteriuria

- The prevalence of asymptomatic bacteriuria varies with age, sex, and comorbid conditions.
- Untreated asymptomatic bacteriuria is not associated with hypertension or renal insufficiency.
- Several guidelines recommend not screening for or treating asymptomatic bacteriuria except in specific patient populations.
- Asymptomatic bacteriuria should be screened for and treated in pregnant women and in patients who are undergoing urologic procedures in which mucosal bleeding is anticipated.
- Treatment of asymptomatic bacteriuria contributes to development of multidrug-resistant symptomatic UTIs.

Principles of Antimicrobial Therapy

Antibiotics have been the mainstay of therapy for UTIs. A decision regarding the antimicrobial selection and the duration of therapy must consider the spectrum of activity of the drug against the known pathogen or the most probable pathogen based on the presumed source of acquisition of infection, whether the infection is judged to be uncomplicated or complicated, potential adverse effects, and cost. The concentration of the antimicrobial agent achieved in blood is not important in treatment of uncomplicated UTIs. However, blood levels are critical in patients with bacteremia and febrile urinary infections consistent with parenchymal involvement of the kidney and prostate.

In patients with renal insufficiency, dosage modifications are necessary for agents that are cleared primarily by the kidneys and cannot be cleared by another mechanism. In renal failure, the kidneys may not be able to concentrate an antimicrobial agent in the urine; therefore difficulty in eradicating bacteria may occur. Urinary tract obstruction may also reduce concentration of antimicrobial agents within the urine.

An often underemphasized but important characteristic is the drug's impact on the bowel and vaginal flora and the hospital bacterial environment. Bacterial susceptibility varies dramatically in patients exposed to antimicrobial agents and in individuals in inpatient and outpatient settings. Each clinician must keep abreast of changes that affect antimicrobial use and susceptibility patterns.

Most important, the decision to initiate antibiotic therapy should not be based on treating a positive urine culture alone; rather clinical presentation, in conjunction with urine testing, should be considered, and we must assess the likelihood that the patient will benefit from or be harmed by antibiosis. As stated by Thomas Hooton in 2012, **“Acute uncomplicated cystitis rarely progresses to severe disease, even if untreated; thus, the primary goal of treatment is to ameliorate symptoms.”** In an era when we are witnessing the increasing resistance of bacterial strains as well as managing the sequelae of inappropriate antibiotic use, decisive clinical judgment and antibiotic stewardship are imperative. As Thomas Finucane wrote, **“Clinicians considering intervention should not ask whether the individual has a real ‘UTI’ but should ask instead whether there is evidence that antibiotic treatment directed at standard bacteriuria is more likely to benefit than harm this individual”**

(Finucane, 2017). It is the firm belief of the authors that these considerations should guide management of UTIs in the contemporary era.

Urinary analgesics are an invaluable adjunct to antibiotic management and may not only reduce symptoms but also shorten the course of antibiotics (Finucane, 2017). In fact a randomized trial involving 500 women younger than 65 years of age compared immediate fosfomycin treatment to ibuprofen alone for the treatment of acute cystitis (Gagyor et al., 2015). At 28 days, the fosfomycin group had received 283 total courses of antibiotics as compared with 94 in the ibuprofen group, corresponding to a significant incidence in the reduction of antibiotic use by 66.5%. An effective urinary analgesic may thus be an important advance in curtailing antibiotic use.

Ecologic Impact and Collateral Damage

Collateral damage refers to the ecologic adverse events associated with antibiotics such as bacterial resistance and selection and/or colonization with multidrug-resistant organisms, which have been associated with the use of broad-spectrum cephalosporins and quinolones (Gupta et al., 2011; Paterson, 2004; Ramphal and Ambrose, 2006). **It is particularly important to consider the collateral impact of antibiotics with respect to uncomplicated cystitis, because (1) there is minimal risk of progression to tissue invasion and sepsis, and (2) this problem is one of the most common sources of antibiotic exposure in otherwise healthy populations, thus potentially magnifying the impact of adverse events when they do occur** (Gupta et al., 2001a,b)**. In the past several years, the frequency and spectrum of antimicrobial-resistant UTIs have increased in the hospital and community.** The increasing frequency of drug resistance has been attributed to combinations of microbial characteristics, bacterial selection pressure caused by antimicrobial use, and societal and technologic changes that enhance the transmission of drug resistance (Shepherd and Pottinger, 2013). Resistance patterns have been shown to vary by geographic location (Manges et al., 2001).

Bacterial resistance may occur because of intrinsic chromosomal-mediated resistance or by acquired chromosomal- or extrachromosomal (plasmid)-mediated resistance caused by exposure of an organism to antimicrobial agents.

Intrinsic chromosomal resistance exists in a bacterial species because of the absence of the proper mechanism on which the antimicrobial agent can act.

Acquired chromosomal resistance occurs during therapy for UTIs. The bacteria susceptible to the administered antimicrobial agent will be eradicated by therapy, but within 24 to 48 hours a repeat urine culture will show high bacterial counts of some resistant mutants. In essence, the antimicrobial therapy has selected the resistant mutant. This phenomenon is most likely to occur when the antimicrobial level in the urine is close to or below the minimal inhibitory concentration of the drug. **Selection of resistant clones in the course of therapy for a previously sensitive bacteriuric population occurs between 5% and 10% of the time, clearly not an insignificant factor.** Underdosing and noncompliance, as well as diuresis induced by increased fluid intake, can contribute to this process. Therefore, when the decision is made that a patient would benefit from antibiotics, the clinician should select an antimicrobial agent with a urinary concentration that exceeds the minimal inhibitory concentration, avoid underdosing, and emphasize patient compliance.

Extrachromosomal-mediated resistance may be acquired and transferable via plasmids, which contain the genetic material for the resistance. **This mechanism of resistance occurs in the bowel flora and is much more common than selection of preexisting mutants in the urinary tract. All antimicrobial classes are capable of causing plasmid-mediated resistance**. In addition, the plasmids carrying the resistant genetic material are transferable within species and across genera. Thus, for example, a patient receiving tetracycline may harbor several bowel strains that are resistant to tetracycline, ampicillin, sulfonamides, and TMP. Because the bowel flora is the major reservoir for bacteria that ultimately colonize the urinary tract, infections that occur after antimicrobial therapy and that can cause plasmid-mediated resistance are commonly caused by organisms with multidrug resistance.

Several bacteria have evolved to develop specific resistance genes to different classes of antibiotics. In 1983 the first report of plasmid-mediated β-lactamases capable of hydrolyzing extended-spectrum cephalosporins was made. They have since been characterized as extended-spectrum β-lactamases (ESBLs) and confer resistance to most β-lactam antibiotics, including third-generation cephalosporins; also, ESBL *E. coli* can have co-resistance to other classes of antibiotics, including fluoroquinolones and aminoglycosides (Pitout and Laupland, 2008; Prakash et al., 2009). In a similar vein, AmpC β-lactamases are cephalosporinases encoded on chromosomes of many Enterobacteriaceae and a few other organisms that confer resistance to broad-spectrum cephalosporins; transmissible plasmids with the AmpC enzyme genes can now appear in bacteria such as *E. coli* that had poor chromosomal expression of this gene (Jacoby, 2009). In 2001 the first *K. pneumoniae* carbapenemase (KPC)–producing bacteria, a group of highly drug-resistant gram-negative bacilli, was isolated. It has since become the most prevalent mechanism of carbapenem resistance in the United States at the time of this writing (Lee et al., 2009). Although *K. pneumoniae* remains the most relevant bacterial species carrying KPCs, the enzyme has been identified in other gram-negative bacilli (Kitchel et al., 2009).

Antimicrobial resistance is influenced by the duration and amount of antimicrobial agent used. For example, documented increased use of fluoroquinolones in the hospital setting has been directly associated with increased resistance of bacteria (particularly *Pseudomonas* spp.) to the fluoroquinolones. Resistance tends to increase the longer the agent is used. Conversely, reduction in duration of therapy and in the amount of the drug used may lead to reemergence of more susceptible strains.

The inappropriate and excessive use of fluoroquinolones for UTIs and other infections has contributed to the growing problem of quinolone resistance among uropathogens (Chen et al., 2012). According to the European Center for Disease Prevention and Control 2015 report, fluroquinolone resistance was noted among 22.8% of *E. coli* strains and 29.7% *K. pneumoniae* isolates (European Centre for Disease Prevention and Control, 2017.)

In institutionalized settings, such as intensive care units or nursing homes, extended-spectrum β-lactamase–producing *E. coli* and *K. pneumoniae* isolates have a reported 40% to 45% resistance rate to quinolones (Itokazu, et al., 1996; Wiener et al., 1999). Furthermore, specific to a transplant unit, where fluoroquinolones are commonly administered prophylactically, *E. coli* resistance can be up to 80%. **Previous use of fluoroquinolones and the presence of underlying urologic diseases were the strongest determinants for UTIs caused by resistant strains** (Ena et al., 1995)**. Last, fluoroquinolone resistance is associated with more frequent multidrug-resistant bacterial strains** and may thus serve as a harbinger of increased individual risk of resistance to first-line antibiotics (Karlowsky et al., 2006).

In fact, many of the adverse events related to antibiotics are also related to a perturbation in commensal microbiomes, such as in the gut and vagina (MacDonald et al., 1993; Vollaard and Clasener, 1994). Antibiotic-related disruption to the intestinal microbiota has been associated with the development of *Clostridium difficile* and colonization with vancomycin-resistant bacteria (Khoruts et al., 2010; Ubeda et al., 2010). Studies in animal models have demonstrated that changes to the intestinal flora after antibiotics can then result in an increased susceptibility to subsequent enteric infection (Sekirov et al., 2008). As far as the implications for the vaginal microbiome, there is a clear association between the risk for vaginal candidiasis and previous treatment with antibiotics (MacDonald et al., 1993). The likelihood of vaginal candidiasis appears directly related to the duration of antibacterial use, particularly with broad-spectrum agents, as well as those who have had repeated episodes of *Candida* infection (Spinillo et al., 1999). Narrowing the spectrum of antibiotic choice and limiting treatment course, particularly in cases of uncomplicated UTIs, are thus instrumental measures in mitigating the systemic implications of treatment.

Antimicrobial Formulary

The mechanism of action, reliable coverage, and common adverse reactions, precautions, and contraindications for antimicrobial agents used in the treatment of UTIs are indicated in Tables 55.4 through 55.7. Bactericidal antibiotics refer to those that cause irreversible death of bacteria, whereas bacteriostatic agents inhibit bacterial replication without killing the organisms (i.e., reversible stoppage).

TABLE 55.4

Bacteriostatic Versus Bactericidal Agents

BACTERIOSTATIC	BACTERICIDIAL
Chloramphenicol	Aminoglycosides
Clindamycin	Quinolones
Macrolides (e.g., azithromycin, erythromycin)	β-lactams
Sulfonamides	Vancomycin
Tetracycline	
Trimethoprim	

Nitrofurantoin is generally bacteriostatic, but it can be bactericidal in high doses and against certain organisms.

TABLE 55.5

Mechanism of Action of Common Antimicrobials Used in the Treatment of Urinary Tract Infections

DRUG OR DRUG CLASS	MECHANISM OF ACTION	MECHANISMS OF DRUG RESISTANCE
β-Lactams (penicillins, cephalosporins, aztreonam)	Inhibition of bacterial cell wall synthesis	Production of β-lactamase Alteration in binding site of penicillin-binding protein Changes in cell wall porin size (decreased penetration)
Aminoglycosides	Inhibition of ribosomal protein synthesis	Downregulation of drug uptake into bacteria Bacterial production of aminoglycoside-modifying enzymes
Quinolones	Inhibition of bacterial DNA gyrase	Mutation in DNA gyrase-binding site Changes in cell wall porin size (decreased penetration) Active efflux
Fosfomycin	Inhibition of bacterial cell wall synthesis	Novel amino acid substitutions or the loss of function of transporters
Nitrofurantoin	Inhibition of several bacterial enzyme systems	Not fully elucidated—develops slowly with prolonged exposure
Trimethoprim-sulfamethoxazole	Antagonism of bacterial folate metabolism	Draws folate from environment (enterococci)
Vancomycin	Inhibition of bacterial cell wall synthesis (at β-lactams)	Enzymatic alteration of peptidoglycan at different point than target

TABLE 55.6

Reliable Coverage of Antimicrobials Used in the Treatment of Urinary Tract Infections of Commonly Encountered Pathogens[a]

ANTIMICROBIAL AGENT OR CLASS	GRAM-POSITIVE PATHOGENS	GRAM-NEGATIVE PATHOGENS
Amoxicillin or ampicillin	*Streptococcus* Enterococci	*Proteus mirabilis*
Amoxicillin with clavulanate	*Streptococcus* Enterococci	*P. mirabilis* *Klebsiella* species
Ampicillin with sulbactam	*Staphylococcus* (not MRSA)	*P. mirabilis* *Haemophilus influenzae,*

	Enterococci	*Klebsiella* species
Antistaphylococcal penicillins	*Streptococcus* *Staphylococcus* (not MRSA)	None
Antipseudomonal penicillins	*Streptococcus* Enterococci	Most, including *Pseudomonas aeruginosa*
First-generation cephalosporins	*Streptococcus* *Staphylococcus* (not MRSA)	*Escherichia coli* *P. mirabilis* *Klebsiella* species
Second-generation cephalosporins (cefamandole, cefuroxime, cefaclor)	*Streptococcus* *Staphylococcus* (not MRSA)	*E. coli, P. mirabilis* *H. influenzae, Klebsiella* species
Second-generation cephalosporins (cefoxitin, cefotetan)	*Streptococcus*	*E. coli, Proteus* species (including indole-positive) *H. influenzae, Klebsiella* species
Third-generation cephalosporins (ceftriaxone)	*Streptococcus* *Staphylococcus* (not MRSA)	Most, excluding *P. aeruginosa*
Third-generation cephalosporins (ceftazidime)	*Streptococcus*	Most, including *P. aeruginosa*
Aztreonam	None	Most, including *P. aeruginosa*
Aminoglycosides	*Staphylococcus* (urine)	Most, including *P. aeruginosa*
Fluoroquinolones	*Streptococcus*[a]	Most, including *P. aeruginosa*
Nitrofurantoin	*Staphylococcus* (not MRSA) Enterococci	Many Enterobacteriaceae (not *Providencia, Serratia, Acinetobacter*) *Klebsiella* species
Fosfomycin	Enterococci	Most Enterobacteriaceae (not *P. aeruginosa*)
Pivmecillinam	None	Most, excluding *P. aeruginosa*
Trimethoprim-sulfamethoxazole	*Streptococcus* *Staphylococcus*	Most Enterobacteriaceae (not *P. aeruginosa*)
Vancomycin	All, including MRSA	None

[a] Depends on the antimicrobial agent.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

TABLE 55.7

Common Adverse Reactions, Precautions, and Contraindications for

Antimicrobial Agents Used in Treatment of Urinary Tract Infection

DRUG OR DRUG CLASS	**COMMON ADVERSE REACTIONS**	**PRECAUTIONS AND CONTRAINDICATIONS**
Amoxicillin or ampicillin	Hypersensitivity (immediate or delayed) Diarrhea (especially with ampicillin), GI upset AAPMC Maculopapular rash (not hypersensitivity) Decreased platelet aggregation	Increased risk of rash with concomitant viral disease, allopurinol therapy
Amoxicillin with clavulanic acid	Increased diarrhea, GI upset with amoxicillin/clavulanic acid	
Ampicillin with sulbactam	Same as with amoxicillin/ampicillin	
Antistaphylococcal penicillins	Same as with amoxicillin/ampicillin GI upset (with oral agents) Acute interstitial nephritis (especially with methicillin)	
Antipseudomonal penicillins	Same as with amoxicillin/ampicillin Hypernatremia (these drugs are given as sodium salt; especially carbenicillin, ticarcillin) Local injection site reactions	Use with caution in patients very sensitive to sodium loading.
Cephalosporins	Hypersensitivity (less than with penicillins) GI upset (with oral agents) Local injection site reactions AAPMC	Should not be used in patients with immediate hypersensitivity to penicillins; may use with caution in patients with delayed hypersensitivity reactions

	Positive Coombs test Decreased platelet aggregation (especially with cefotetan, cefamandole, cefoperazone)	
Aztreonam	Hypersensitivity (less than with penicillins)	Less than 1% incidence of cross-reactivity in penicillin- or cephalosporin-allergic patients; may be used with caution in these patients
Aminoglycosides	Ototoxicity: vestibular and auditory components Nephrotoxicity: nonoliguric azotemia Neuromuscular blockade with high levels	Avoid in pregnant patients, except in pyelonephritis. Avoid if possible in patients with severely impaired renal function, diabetes, or hepatic failure. Use with caution in myasthenia gravis patients (because of potential for neuromuscular blockade). Use with caution with other potentially ototoxic and nephrotoxic drugs.
Fluoroquinolones	Mild GI effects; dizziness, lightheadedness; photosensitivity Central nervous system effects, including dizziness, tremors, confusion, mood disorder, hallucinations Tendon rupture	Avoid in children or pregnant patients because of arthropathic effects. Concomitant antacid, iron, zinc, or sucralfate use dramatically decreases oral absorption; use another antimicrobial agent or discontinue sucralfate use while taking quinolones. Space administration of quinolones from antacids, iron, or zinc products by at least 2 h to ensure adequate absorption. Ensure adequate patient hydration. These agents can significantly increase theophylline plasma levels (ciprofloxacin and enoxacin seem to have a greater effect than norfloxacin or

		ofloxacin); avoid quinolones or monitor theophylline levels closely. These agents can lower seizure threshold; avoid in patients with epilepsy and in patients with other risk factors (medications or illness) that may lower the seizure threshold. Monitor glucose levels in patients taking antidiabetic agents because hypoglycemia and hyperglycemia have been reported in patients treated concurrently with fluoroquinolones and antidiabetic agents. These agents can enhance warfarin effects; closely monitor coagulation tests.
Fosfomycin	Headache GI upset Vaginitis	Hypersensitivity to fosfomycin or any component of the formulation
Pivmecillinam	Rash GI upset	Use with caution in patients with penicillin hypersensitivity.
Nitrofurantoin	GI upset Peripheral polyneuropathy (especially in patients with impaired renal function, anemia, diabetes, electrolyte imbalance, vitamin B deficiency, and debilitated) Hemolysis in patients with G6PD deficiency Pulmonary hypersensitivity reactions can range from acute to chronic and include cough, dyspnea, fever, and	Do not use in patients with low creatinine clearance (<50 mL/min) because adequate urine concentrations will not be achieved. Monitor long-term patients closely. Avoid concomitant probenecid use, which blocks renal excretion of nitrofurantoin. Avoid concomitant magnesium or quinolones, which are antagonistic to nitrofurantoin.

	interstitial changes.	
Trimethoprim-sulfamethoxazole	Hypersensitivity, rash GI upset Photosensitivity Hematologic toxicity (AIDS patients)	Higher incidence of all adverse reactions occurs in AIDS patients and in the elderly. Avoid in pregnant patients. Avoid in patients receiving warfarin; concomitant use can significantly elevate prothrombin time.
Vancomycin	"Red-man syndrome": flushing, fever, chills, rash, hypotension (histaminic effect) Nephrotoxicity and/or ototoxicity when combined with other nephrotoxic and/or ototoxic drugs Local injection site reactions	Use with caution with other potentially ototoxic and nephrotoxic drugs.

AAPMC, Antimicrobial-associated pseudomembranous colitis; *AIDS,* acquired immunodeficiency syndrome; *GI,* gastrointestinal; *G6PD,* glucose-6-phosphate dehydrogenase.

Data from McEvoy GK, editor: *American Hospital Formulary Service drug information,* Bethesda, MD, 1995, American Society of Health-System Pharmacists.

Nitrofurantoin

Nitrofurantoin is effective against most common uropathogens. It is rapidly excreted from the urine but does not obtain therapeutic levels in most body tissues, including the gastrointestinal (GI) tract. Therefore it is not useful for upper tract, complicated infections, or blood-borne infections (Wilhelm and Edson, 1987)**. It has minimal effects on the resident bowel and vaginal flora.** Acquired bacterial resistance to this drug is exceedingly low. Nitrofurantoin can cause GI upset and rare pulmonary issues, such as pulmonary fibrosis, when used chronically. Nitrofurantoin should also be avoided in patients with suspicion of or known glucose-6-phosphate dehydrogenase (G6PD) deficiency because it can lead to hemolytic anemia. It had always been recommended that nitrofurantoin be avoided in patients with chronic renal insufficiency, defined as a CrCl less than 60 mL/min, because of lack of efficacy from poor renal concentrating ability. However, in the 2015 American Geriatric

Society Beers Criteria, this threshold was reduced to 30 mL/min because of new data regarding its effectiveness in certain populations with renal impairment. Despite this revision, it remains prudent to use nitrofurantoin with caution in patients with significant renal impairment, particularly for long courses. In fact, Geerts, et al. (2013) found that in a cohort of 21,317 women treated with 3 to 10 days of nitrofurantoin for UTI, renal impairment (defined as CrCl 30–50 mL/min) was not significantly associated with treatment ineffectiveness; nevertheless, a significant association was noted between renal impairment (CrCl < 50 mL/min) and pulmonary adverse events leading to hospitalization.

The Beers Criteria strongly recommend against the *long-term* use of nitrofurantoin for the purposes of antibiotic suppression, founded on the potential adverse events described earlier; nevertheless, **there is no specific recommendation against the *short-term* use of these agents within a carefully selected geriatric population, specifically those with normal renal function.** It is the authors' shared opinion that this agent can still remain a first-line treatment option for the acute management of uncomplicated cystitis within select elderly populations, although the categorical recommendation against long-term usage has created insurance coverage barriers to prescribing nitrofurantoin even for limited courses in these patients.

Trimethoprim-Sulfamethoxazole

The combination of TMP-SMX has been one of the most widely used antimicrobial agents for the treatment of acute UTIs. TMP-SMX attains therapeutic levels in most tissues and is effective against most common uropathogens, with the notable exception of *Enterococcus* and *Pseudomonas* spp. TMP-SMX is inexpensive and has minimal adverse effects on the bowel flora. Disadvantages are relatively common adverse effects, consisting primarily of rashes and GI complaints (Cockerill and Edson, 1991). Stevens-Johnson syndrome and toxic epidermal necrolysis are rare and potentially life-threatening, blistering skin reactions that have been associated with TMP-SMX. In fact, one contemporary Canadian retrospective review analyzing the inciting agent for the 64 documented cases seen at their regional hospital between 2001 and 2011 identified TMP-SMX as the antibiotic most often associated with this reaction; it was implicated in 4 of the 64 patients reviewed (6%) (Miliszewski et al., 2016).

Fosfomycin

Fosfomycin, an oral bactericidal antimicrobial agent similar to phosphonic acid in chemical structure, is active against most uropathogens. Its major benefit is its limited cross-resistance between most other common antibacterial agents, as well as its efficacy against the majority of gram-negative organisms and vancomycin-resistant *Enterococcus* (VRE). Further, it has been shown to be effective as a single-dose agent when used as an empirical treatment for uncomplicated cystitis. It is an excellent oral option for MDR bacteria that would otherwise necessitate treatment with intravenous antibiotics. It is generally well tolerated with low incidences of GI upset and headache and very rare adverse events seen in multiple trials (Patel et al., 1997). Fosfomycin should not be used in the setting of urosepsis/blood-borne infections. Currently, in the United States a 3-g sachet of fosfomycin costs $70 to $90 or more, depending on the insurance coverage; this expense may preclude its use in some patients.

Fluoroquinolones

Fluoroquinolones share a common predecessor in nalidixic acid and inhibit DNA gyrase, a bacterial enzyme integral to replication. The fluoroquinolones have a broad spectrum of activity that makes them ideal for the empirical treatment of UTIs. **They are effective against Enterobacteriaceae and *P. aeruginosa*. Activity is also high against *S. aureus* and *S. saprophyticus*, but, in general, antistreptococcal coverage is marginal.** Most anaerobic bacteria are resistant to these drugs; therefore the normal vaginal and bowel flora are not altered (Wright et al., 1993). **Bacterial resistance initially appeared to be uncommon but has increased because of indiscriminate use of these agents** (Vromen et al., 1999; Wright et al., 1993).

These drugs are not nephrotoxic, but renal insufficiency prolongs the serum half-life, requiring adjusted dosing in patients with creatinine clearances of less than 30 mL/min. Among the adverse reactions reported for fluoroquinolones, GI disturbances are the most common, and this is likely related to the collateral damage to commensal microbiota in the gut (Stewardson et al., 2015). Hypersensitivity, skin reactions, central and peripheral nervous system reactions, and even acute renal failure have been reported (Hootkins et al., 1989). In addition, serious central nervous system side effects, anxiety/depression, hallucinations, confusion, and suicidal thoughts have been cited (FDA Drug Safety Communication, 2016).

In 2008 the US Food and Drug Administration (FDA) announced a black box warning of tendon ruptures associated with fluoroquinolones. In 2013 it

added a risk of irreversible nerve damage to the warning. In 2015 the FDA acknowledged the existence of fluoroquinolone-associated disability (FQAD) in 178 patients, with chronic pain reported as the most common symptom. Although it does not affect the majority of patients, FQAD may be "underappreciated" (Tennyson and Averch, 2017). Some have speculated that mitochondrial damage is responsible for the serious adverse effects, but there is no consensus about this theory (Marchant, 2018).

Achilles tendon disorders, including rupture, have been estimated to occur in 20 cases per 100,000 and therefore fluoroquinolone use should be discontinued at the first sign of tendon pain (Greene, 2002). Drug-induced tendinopathy is listed as a class effect of fluoroquinolones; indeed, there is a 3.8-fold increased risk of Achilles tendinopathy compared with use of other antibiotics (Chhajed et al., 2002). A recent study determined that factors that contribute to an increased risk of sustaining an Achilles tendon disorder while taking a fluoroquinolone include advanced age, chronic renal failure, male gender, normal body mass index (BMI), and concurrent use of corticosteroids (Godoy-Santos et al., 2018). The mechanism of tendon rupture is unclear, but ciprofloxacin stimulates matrix-degrading protease activity from fibroblasts and exerts an inhibitory effect on fibroblast metabolism and synthesis of matrix ground substance, factors that may contribute to tendinopathy (Williams, et al., 2000). Other soft tissue and peripheral nervous system side effects reported with fluoroquinolones include paresthesias, myalgias, and arthralgias (2016). Administration of the fluoroquinolones to immature animals has caused damage to the developing cartilage; therefore they are currently contraindicated in children, adolescents, and pregnant or nursing women (Christ et al., 1988). More research is needed to better characterize side effects associated with fluoroquinolone usage and understand why certain people are susceptible to these adverse results (Marchant, 2018).

Because of the disabling and potentially irreversible side effects of these drugs on soft tissue and the nervous system, in 2016 the FDA revised the boxed warning on these products to reflect the fact these agents should be prescribed sparingly. According to this warning, "fluoroquinolones should be reserved for use in patients who have no other treatment options for… uncomplicated urinary tract infections because the risk of these serious side effects generally outweighs the benefits in these patients." A new FDA warning issued in 2018 warns against the development of mental health side effects, specifically agitation, disorientation, delirium, memory impairment,

nervousness, and problems with attention. In addition, the FDA expressed concerns about blood sugar disturbances associated with fluoroquinolone use (FDA, 2018b). Later in 2018 the FDA issued a warning about an increased risk of aortic dissection associated with fluoroquinolone use (FDA, 2018a).

There are important drug interactions associated with the fluoroquinolones. The World Health Organization (WHO) warns of rare increases in the anticoagulant effects of Coumadin when taken with fluoroquinolones. Antacids containing magnesium or aluminum interfere with absorption of fluoroquinolones (Davies et al., 1972). Certain fluoroquinolones (enoxacin and ciprofloxacin) elevate plasma levels of theophylline and prolong its half-life (Wright et al., 1993).

Cephalosporins

Three generations of cephalosporins have been used for the treatment of acute UTIs (Wilhelm and Edson, 1987). In general, as a group, activity is high against Enterobacteriaceae and poor against enterococci. First-generation cephalosporins have greater activity against gram-positive organisms, as well as common uropathogens such as *E. coli* and *K. pneumoniae,* whereas second-generation cephalosporins have activity against anaerobes. Third-generation cephalosporins are more reliably active against community-acquired and nosocomial gram-negative organisms than other β-lactam antimicrobials. First-generation cephalosporins such as cephalexin can be prescribed in doses that range from 500 mg twice daily to three or four times daily for 3 to 7 days for uncomplicated cystitis; dosing is highly variable depending on the source. Fourth- and fifth-generation cephalosporins can be used for complicated UTIs.

Aminopenicillins

Ampicillin and amoxicillin have been used often in the past for the treatment of UTIs, but the emergence of resistance in 40% to 60% of common urinary isolates has lessened the usefulness of these drugs (Gupta et al., 2011; Hooton and Stamm, 1991). The effects of these agents on the normal bowel and vaginal flora can predispose patients to reinfection with resistant strains and often lead to candidal vaginitis (Iravani, 1991). The addition of the β-lactamase inhibitor clavulanate to amoxicillin greatly improves activity against β-lactamase–producing bacteria resistant to amoxicillin alone. However, its high cost and frequent GI side effects limit its usefulness. The extended-spectrum penicillin derivatives (e.g., pivmecillinam, piperacillin, mezlocillin, azlocillin) retain ampicillin's activity against enterococci and offer activity against many ampicillin-resistant gram-negative bacilli. **This makes them attractive agents for use in patients with nosocomially acquired UTIs and as the initial parenteral treatment of acute uncomplicated pyelonephritis acquired outside of the hospital, although less-expensive agents are equally effective.**

Aminoglycosides

When combined with TMP-SMX or ampicillin, aminoglycosides are the first drugs of choice for febrile UTIs. Their nephrotoxicity and ototoxicity are well recognized; therefore careful monitoring of patients for renal and auditory impairment associated with infection is indicated. Once-daily aminoglycoside regimens have been instituted to maximize bacterial killing by optimizing the peak concentration-to-minimal inhibitory concentration ratio and reduce the potential for toxicity (Fig. 55.11; Nicolau et al., 1995). Administering an aminoglycoside as a single daily dose can take advantage not only of its concentration-dependent killing ability but also of two other important characteristics: time-dependent toxicity and a more prolonged postantimicrobial effect (Gilbert, 1991; Zhanel et al., 1991a,b). The regimen consists of a fixed 5 to 7-mg/kg dose of gentamicin or 5 to 7 mg/kg tobramycin. Subsequent interval adjustments are made by using a single concentration in serum and a nomogram designed for monitoring of once-daily therapy (Fig. 55.12). Antimicrobial doses are given at the interval determined by the drug concentration of a sample obtained after the start of the initial infusion. For example, if the serum concentration was 7 mg/mL 10 hours after the start of the infusion, subsequent 7-mg/kg doses would be given every 36 hours. This regimen is clinically effective, reduces the incidence of nephrotoxicity, and provides a cost-effective method for administering aminoglycosides by reducing ancillary service times and serum aminoglycoside determinations.

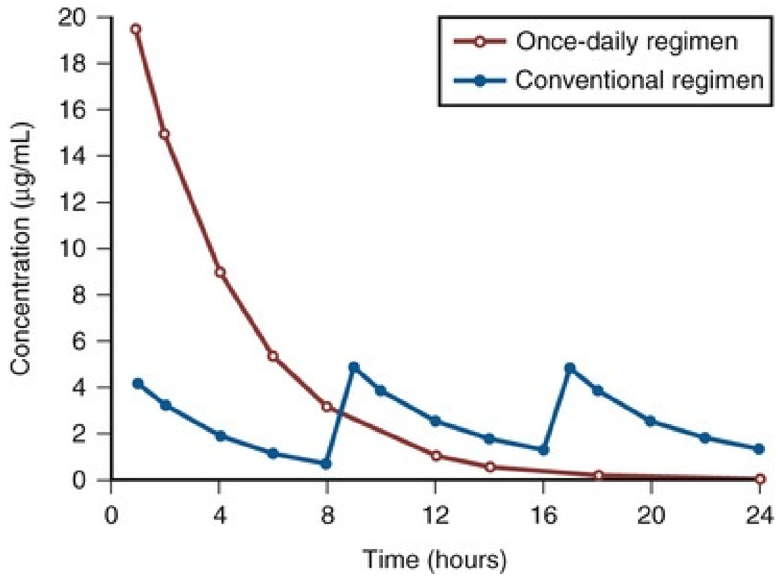

FIG. 55.11 Simulated concentration-versus-time profile of once-daily (7 mg/kg/24 h) and conventional (1.5 mg/kg/8 h) regimens for patients with normal renal function. (From Nicolau DP, Freeman CD, Belliveau PP, et al.: Experience with a once-daily aminoglycoside program administered to 2,184 adult patients. *Antimicrob Agents Chemother* 39:650–655, 1995.)

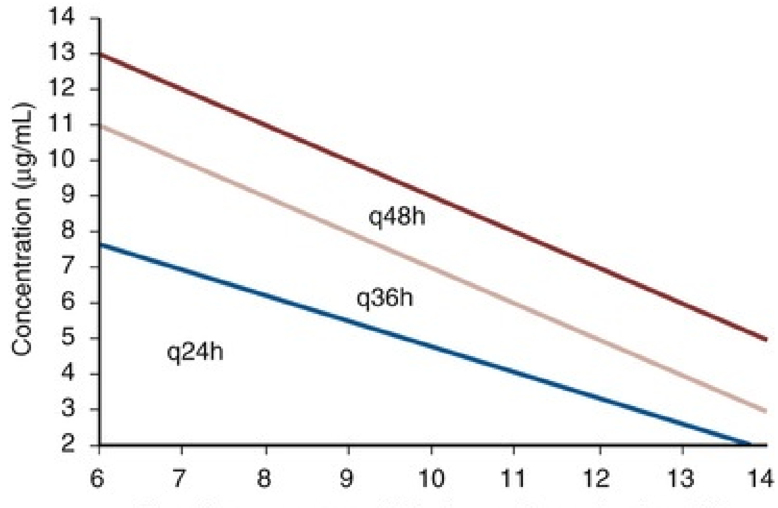

FIG. 55.12 Once-daily aminoglycoside nomogram for gentamicin and tobramycin at 7 mg/kg. (From Nicolau DP, Freeman CD, Belliveau PP, et al.: Experience with a once-daily aminoglycoside program administered to 2,184 adult patients. *Antimicrob Agents Chemother* 39:650–655, 1995.)

Aztreonam

Aztreonam has a similar spectrum of activity as the aminoglycosides, and as with all β-lactams, it is not nephrotoxic. However, its spectrum of activity is less broad than the third-generation cephalosporins. **It should be used primarily in patients who have penicillin allergies.**

Pivmecillinam

Pivmecillinam is a penicillin-like β-lactam antibiotic that is the prodrug of mecillinam. It has high activity against gram-negative organisms and is primarily used in Nordic countries for empirical treatment of uncomplicated cystitis. **It is not currently available in the United States,** but it has been shown to have low resistance patterns (roughly 2% of *E. coli*) as well as being safe and effective (Grainger et al., 1982).

Choice of Antimicrobial Agents

Many antimicrobial agents have been shown to be effective in the treatment of UTIs. **Factors important in aiding selection of empirical therapy include whether the infection is complicated or uncomplicated; the spectrum of activity of the drug against the probable pathogen; a history of hypersensitivity; potential side effects, including renal and hepatic toxicity; the ecologic impact of antibiotic choice; and cost.** The bacterial susceptibility and cost of the drug vary dramatically among inpatient and outpatient settings throughout the country. Therefore it is imperative that each clinician keep abreast of changes in bacterial susceptibility via regional antibiograms as well as cost patterns and use current information when choosing antimicrobial agents.

As mentioned earlier, antibiotic-related disruption to the intestinal microbiota can result in GI side effects, specifically diarrhea. *C. difficile* infections (CDIs) are particularly concerning. In recent years CDIs have become more common and more resistant to treatment. In 2011 453,000 CDIs were diagnosed, resulting in 29,000 deaths in the United States (Lessa et al., 2015). Antibiotics most likely to cause CDI include cephalosporins, clindamycin, carbapenems, trimethoprim/sulfamethoxazole, fluoroquinolones, and penicillin combinations. Macrolides, tetracyclines, and aminoglycosides are not associated with CDI (Slimings, 2014). The diagnosis of CDI requires the presence of diarrhea (diagnosed as greater than or equal to 3 unformed stools in 24 hours) or radiologic evidence of ileus or toxic megacolon and a stool test that is positive for toxigenic *C. difficile* or its toxins or histopathologic or colonoscopic evidence of pseudomembranous colitis. Treatment of CDI should be guided by the severity of illness and the risk of recurrence or complications. Metronidazole and vancomycin are the treatment of choice for CDI; recent data reveal higher treatment failure rates associated with metronidazole with increasing disease severity. Thus, with more mild cases metronidazole is the preferred treatment of choice, whereas with more severe cases vancomycin is recommended (Bagdasarian et al., 2015).

Duration of Therapy

The duration of therapy needed to cure a UTI appears to be related to a number of variables, including the extent and duration of tissue invasion, the bacterial concentration in urine, the achievable urine concentration of the antimicrobial agent, and risk factors (see later) **that impair the host and natural defense mechanisms.**

Key Points: Principles of Antimicrobial Therapy

- Antimicrobial resistance is increasing because of excessive use.
- Antimicrobial selection should be influenced by efficacy, safety, cost, and compliance.
- The choice of the agent as well as the duration of therapy are critical in preventing the perpetuation of antimicrobial resistance as well as adverse events related to treatment.

Bladder Infections

Uncomplicated Cystitis

The overwhelming majority of infections encountered in urology are acute uncomplicated cystitis. Often these infections are treated by practitioners other than urologists. **Most cases of uncomplicated cystitis occur in women. Each year, approximately 10% of women report having had a UTI, and more than 50% of all women have at least one such infection in their lifetime** (Foxman et al., 2000). Uncomplicated cystitis occasionally occurs in prepubertal girls, but it increases greatly in incidence in late adolescence and during the second and fourth decades of life. Twenty-five to 30 percent of women 20 to 40 years of age have a history of UTIs (Kunin, 1961). **Although it is much less common, young men may also experience acute cystitis without underlying structural or functional abnormalities of the urinary tract** (Krieger et al., 1993). Risk factors (Box 55.9) include sexual intercourse and use of spermicides (Foxman, 2002; Handley et al., 2002; Hooton et al., 1996). Sexual transmission of uropathogens has been suggested by demonstrating identical *E. coli* in the bowel and urinary flora of sex partners (Johnson and Stamm, 1989).

Box 55.9

Risk Factors for Urinary Tract Infections

Reduced Urine Flow

- Outflow obstruction, prostatic hyperplasia, prostatic carcinoma, urethral stricture, foreign body (calculus)
- Neurogenic bladder
- Inadequate fluid uptake (dehydration)

Promote Colonization

- Sexual activity—increased inoculation
- Spermicide—increased binding
- Estrogen depletion—increased binding

Antimicrobial agents—decreased indigenous flora

Facilitate Ascent

Catheterization
Urinary incontinence
Fecal incontinence
Residual urine with ischemia of bladder wall

***E. coli* is the causative organism in 75% to 90% of cases of acute cystitis in young women** (Latham et al., 1985; Ronald, 2002)**. *S. saprophyticus*, a commensal organism of the skin, is the second most common cause of acute cystitis in young women, accounting for 10% to 20% of these infections** (Jordan et al., 1980). **Other organisms less commonly involved include *Klebsiella, Proteus,* and *Enterococcus* spp. In men, *E. coli* and other Enterobacteriaceae are the most commonly identified organisms.**

Clinical Presentation

The validated UTI Symptom Assessment questionnaire includes seven symptoms that are most likely reported in association with a UTI: frequency, urgency, painful urination, incomplete emptying, suprapubic pain/pressure, low back pain, and hematuria. In addition to identifying the presence or absence of individual patient-reported symptoms, the degree of severity and bother are also assessed with this questionnaire (Clayson et al., 2005). Cystitis is a superficial infection of the bladder mucosa, so fever, chills, and other signs of dissemination are usually not present.

Although many patients complain of foul-smelling or cloudy urine when requesting treatment for a UTI, studies have not identified these symptoms as reliable indicators of the presence of a UTI, particularly in the absence of specific urinary symptoms. If patients have one or both of these symptoms, yet none of the earlier-mentioned classic symptoms, they should be encouraged to hydrate vigorously and then reassess.

Studies suggest that having more than one symptom raises the likelihood of being diagnosed with a UTI. However, dysuria alone is the most reliable indicator of UTI; when present it contributes to higher severity and bother scores compared with other typical UTI symptoms (Dune et al., 2017). Diagnosis of a UTI can be challenging because many patients complain of symptoms such as frequency, urgency, or incontinence at baseline associated with other lower urinary tract pathology. Thus, when critically evaluating a patient with symptoms suggestive of UTI, clinicians must establish whether the symptoms are different from their baseline voiding dysfunction symptoms. In addition, patients often complain of “burning,” which may be burning associated with urination (dysuria), or burning in the vaginal or pelvic area that is present irrespective of voiding. If patients complain of “burning,” it is important to have them articulate their complaint beyond just “burning.”

A review of nine studies (published between 1965 and 2001) investigating the accuracy of history and physical examination in properly detecting acute uncomplicated UTI determined that **in the absence of vaginal discharge or irritation, the combination of symptoms of dysuria and frequency can predict the presence of a UTI in more than 90%. Overall, the probability of having a UTI is increased when a patient experiences frequency, dysuria, hematuria, and back pain, along with demonstrating CVAT on exam** (Bent et al., 2002).

Similarly, a recent meta-analysis compiled 16 studies encompassing 3711 patients in an effort to ascertain the diagnostic accuracy of individual symptoms by correlating them to urine culture results. In this investigation, the presence of frequency, dysuria, hematuria, nocturia, and urgency increased the probability of having a UTI, whereas the presence of vaginal discharge decreased the likelihood of having a UTI. When hematuria was associated with nitrites on a dipstick, the probability of having a UTI was at least 90% (Giesen et al., 2010).

Overall, acute onset of dysuria and acute change in baseline voiding symptoms are most consistent with a diagnosis of acute uncomplicated cystitis.

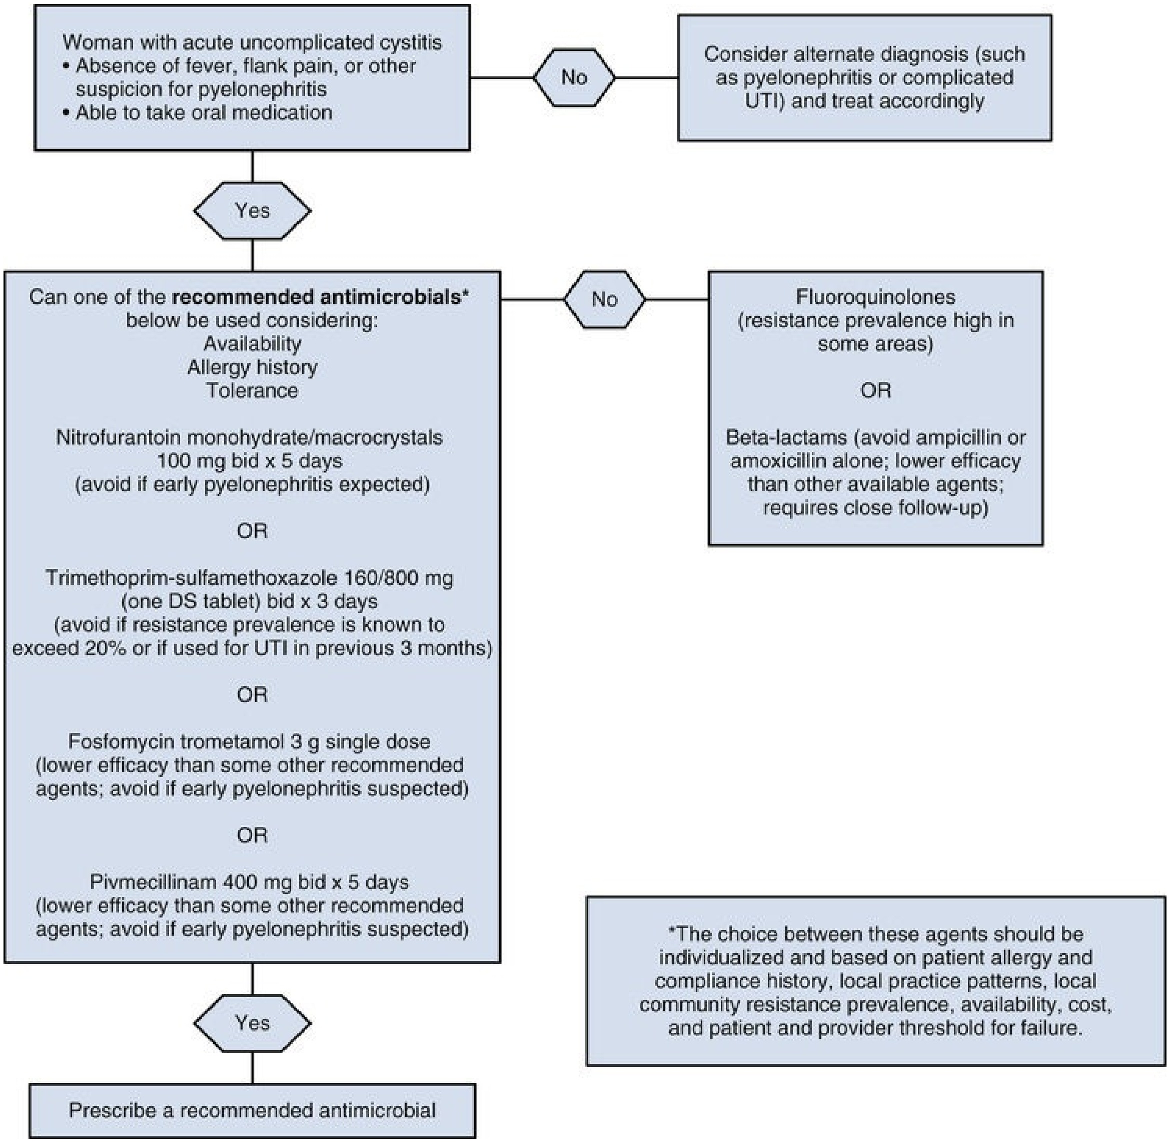
Laboratory Diagnosis

See prior discussion of urine testing in the evaluation section.

Management

Antimicrobial Selection.

Oral antimicrobial agents for treatment of acute uncomplicated cystitis are outlined in Fig. 55.13. The recommendations set forth for the management of uncomplicated cystitis in women, described herein, are based on the IDSA and European Society of Microbiology and Infectious Diseases guidelines statement (Gupta et al., 2011). **In general, these treatment algorithms should inform** management, and the ultimate choice of agent should be individualized based on allergy status, projected compliance, local antibiograms/ practice patterns, availability, and cost.



Woman with acute uncomplicated cystitis
• Absence of fever, flank pain, or other suspicion for pyelonephritis
• Able to take oral medication
No
Consider alternate diagnosis (such as pyelonephritis or complicated UTI) and treat accordingly
Yes
Can one of the **recommended antimicrobials*** below be used considering:
Availability
Allergy history
Tolerance
Nitrofurantoin monohydrate/macrocrystals 100 mg bid x 5 days (avoid if early pyelonephritis expected)
OR
Trimethoprim-sulfamethoxazole 160/800 mg (one DS tablet) bid x 3 days (avoid if resistance prevalence is known to exceed 20% or if used for UTI in previous 3 months)
OR
Fosfomycin trometamol 3 g single dose (lower efficacy than some other recommended agents; avoid if early pyelonephritis suspected)
OR
Pivmecillinam 400 mg bid x 5 days (lower efficacy than some other recommended agents; avoid if early pyelonephritis suspected)
No
Fluoroquinolones (resistance prevalence high in some areas)
OR
Beta-lactams (avoid ampicillin or amoxicillin alone; lower efficacy than other available agents; requires close follow-up)
*The choice between these agents should be individualized and based on patient allergy and compliance history, local practice patterns, local community resistance prevalence, availability, cost, and patient and provider threshold for failure.
Yes
Prescribe a recommended antimicrobial

FIG. 55.13 IDSA-recommended treatment of acute uncomplicated cystitis.

Nitrofurantoin has maintained an excellent level of activity over 4 decades and is well tolerated. Nitrofurantoin (100 mg twice daily for 5 days) is an appropriate choice for first-line therapy because of minimal resistance and propensity for ecologic adverse side effects; its efficacy is comparable with 3 days of TMP-SMX.

TMP and TMP-SMX (DS twice daily for 3 days) are effective and

inexpensive agents for empirical therapy, resulting in bacteriologic cure (i.e., eradication of the pathogen from the urine) within 7 days after the start of treatment in approximately 94% of women (Warren et al., 1999). **They are recommended in areas where the prevalence of resistance to these drugs among *E. coli* strains causing cystitis is less than 20%** (Gupta et al., 2011). When used alone, TMP is as efficacious as TMP-SMX and is associated with fewer side effects, presumably because of the absence of the sulfa component (Harbord and Gruneberg, 1981). It can be prescribed to patients who are allergic to sulfa. However, TMP can cause hypersensitivity and rashes that may be erroneously attributed to sulfa (Alonso et al., 1992).

Fosfomycin trometamol (3 g in a single dose) is an appropriate choice for therapy where it is available because of minimal resistance and propensity for collateral damage, but it may have inferior efficacy compared with standard short-course regimens according to data submitted to the FDA and summarized in the Medical Letter (1997; Gupta et al., 2011).

Pivmecillinam (400 mg twice daily for 3 to 7 days) is an appropriate choice for therapy in regions where it is available (availability limited to some European countries; not licensed and/or available for use in North America) because of minimal resistance and propensity for collateral damage, but it may have inferior efficacy compared with other available therapies (A-I; Gupta et al., 2011).

The **fluoroquinolones** have been used in the management of uncomplicated cystitis in the past, and they are effective in 3-day regimens (Gupta et al., 2011). **They have a high propensity for collateral damage (i.e., ecological adverse effects, such as drug resistance) and should be reserved as antimicrobials of last resort for acute cystitis; indeed this is in agreement with the FDA warning mentioned in an earlier section** (2016; Gupta et al., 2011).

β-lactam agents (such as amoxicillin-clavulanate, cefdinir, cefaclor, and cefpodoxime-proxetil) remain second-line treatment options for uncomplicated cystitis and can be used in 3- to 7-day regimens (Gupta et al., 2011).

Duration of Therapy.

Three-day therapy is the preferred regimen for uncomplicated cystitis in women (Norrby, 1990; Warren et al., 1999). In an excellent review of more than 300 separate clinical trials of single-dose, 3-day, or 7-day treatment with TMP, TMP-SMX, fluoroquinolones, and β-lactam antimicrobial therapies, it was concluded that, irrespective of the antimicrobial used, 3-day therapy is more effective than single-dose therapy. Three-day therapy with TMP-SMX and TMP has been associated with cure rates similar to longer courses of therapy and an incidence of adverse effects about as low as that seen with single-dose therapy and lower than seen with longer courses of therapy (Charlton et al., 1976; Kunin, 1985; McCue, 1986; Warren et al., 1999). Because 7-day therapy often causes more adverse effects, it is recommended only for women with symptoms of 1 week or more, men, and individuals with possible complicating factors. Other durational variations include nitrofurantoin 5-day therapy and fosfomycin single-dose therapy.

Seven-day therapy is the preferred regimen for cystitis in men.

Cost of Therapy.

The cost of treating a UTI involves not only the initial evaluation and cost of the drug but also what occurs subsequently. The most important prediction of high cost-effectiveness is high efficacy against the most common urinary pathogen, *E. coli*. The lower the effectiveness against this bacterium, the greater the number of revisits, cases of progression to pyelonephritis, and follow-up costs. Antimicrobial cost is a poor prediction of cost-effectiveness (Rosenberg, 1999).

Follow-Up

Approximately 90% of women are asymptomatic within 72 hours after initiating antimicrobial therapy (Fihn et al., 1985)**. A follow-up visit or culture is not required in women who are asymptomatic after therapy. Further urologic evaluation is unnecessary in women who respond to therapy** (Abarbanel et al., 2003; Lipsky, 1989). **However, UTIs in most men should be considered complicated until proven otherwise.** Andrews et al. (2002) showed that approximately 50% of men with UTIs have a significant abnormality. Furthermore, if a patient does not respond to therapy, appropriate microbiologic urologic evaluations should be undertaken for the causes of unresolved and complicated UTIs.

Compliance With Recommended Agents.

Despite the compelling argument for the purposeful and selective use of antibiotic therapy with respect to the treatment of uncomplicated cystitis, practice patterns within the prescribing community as a whole have yet to change. In a recent questionnaire distributed to physicians, including non-urologists, more than half of the 260 respondents were not familiar with the

IDSA guidelines, and 30% did not recommend a first-line agent for the treatment of uncomplicated cystitis (Ditkoff et al., 2017). This suggests that further education and outreach efforts are critical to ensure all practitioners managing patients with uncomplicated cystitis are practicing the standard of care; only this way can the negative ecologic impact of inappropriate antibiotic use be mitigated on a population level.

Complicated Urinary Tract Infections

Complicated UTIs are those that occur in a patient with a compromised urinary tract or that are caused by a very resistant pathogen (Table 55.8). **These complicating factors may be readily apparent from the severity of the presenting illness or the past medical history. However, they may not be obvious at first and may only become evident from subsequent failure of the patient to respond to appropriate therapy** (see later discussion on unresolved or recurrent UTIs).

TABLE 55.8

Host Factors Classifying a Urinary Tract Infection as Complicated

COMPLICATION	EXAMPLES
Anatomic abnormality	Cystocele, fistula, diverticulum
Iatrogenic	Nosocomial infection, surgery, indwelling catheter
Urinary tract obstruction	Bladder outlet obstruction, ureteropelvic junction obstruction, ureteral stricture
Voiding dysfunction	Neurologic disease, pelvic floor dysfunction, vesicoureteral reflux, incontinence, high postvoid residual
Other	Pregnancy, urolithiasis, diabetes, other immunosuppression

Data from Dason S, Dason J, Kappor A, et al.: Guidelines for the diagnosis and management of recurrent urinary tract infections in women. *Can Urol Assoc J* 5(5):316–322, 2011.

The clinical spectrum ranges from mild cystitis to life-threatening kidney infections and urosepsis (kidney infections and urosepsis are discussed subsequently). These infections can be caused by a broad range of bacteria with resistance to multiple antimicrobial agents. Therefore urine cultures are mandatory to identify the bacteria and its antimicrobial susceptibility.

Because of the wide range of host conditions and pathogens and a lack of adequate controlled trials, guidelines for empirical therapy are limited. For patients with mild to moderate illness who can be treated as an outpatient with oral therapy, 10 to 14 days of fluoroquinolones have traditionally been recommended because of their concentration in the urine and good tissue penetration (Stamm and Hooton, 1993); however, emerging resistance patterns to this class of antibiotics as well as concerns about side effects will likely change prior practice patterns.

For patients requiring hospitalization, IV antimicrobials should be administered based on the susceptibility patterns of the known uropathogens at that institution.

Because therapy will be compromised without addressing complicating factors, every effort should be made to correct any underlying urinary tract abnormalities, such as obstruction, and treat host factors that exacerbate the infection.

Therapy is usually continued for 10 to 14 days on culture-specific antibiotics and switched from parenteral to oral therapy when the patient is afebrile and clinically stable. Repeat urine cultures should be performed if the patient fails to respond to therapy.

Emphysematous Cystitis

Emphysematous cystitis is a rare and potentially life-threatening form of complicated cystitis that is associated with a mortality rate of up to 7% (Amano and Shimizu, 2014). Early medical therapy is important in achieving a favorable outcome and avoiding the need for surgical intervention. The pathognomonic finding of this disease process is gas noted within the wall on cross-sectional imaging. Emphysematous cystitis is typically observed in elderly women (60–70 years of age) with poorly controlled diabetes; additional risk factors include any condition that may predispose to incomplete emptying and lower urinary stasis, such as neurogenic bladder and bladder outlet obstruction. Although various microorganisms have been associated with this disease process, *E. coli* (60%) and *K. pneumoniae* (10%–20%) are most commonly implicated (Amano and Shimizu, 2014).

Clinical Presentation.

The clinical signs and symptoms are variable, ranging from asymptomatic (reported in up to 7%) to overt sepsis (Kuo et al., 2009; Wortmann and Fleckenstein, 1998). The most common symptom in these patients is abdominal pain (80%) (Grupper et al., 2007) followed by gross hematuria (60%), and obstructive urinary symptoms (10%) (Yoshida et al., 2010). The presence of fever is variable and has been reported in 30% to 50% of these patients (Amano and Shimizu, 2014).

Radiologic Findings.

The characteristic feature on plain radiograph involves curvilinear areas of increased radiolucency delineating the bladder wall and separate from the rectal gas posteriorly; the distribution of the air has been described as a cobblestoned or "beaded necklace" appearance, reflecting the irregular submucosal blebs (Grayson et al., 2002). A CT scan of the pelvis will also show air pocketed diffusely within the bladder wall, and possibly intraluminally; a CT scan is necessary to make the diagnosis and exclude other sources of pelvic air such as a fistula, trauma, or gangrene of adjacent structures (Amano and Shimizu, 2014; Fig. 55.14).

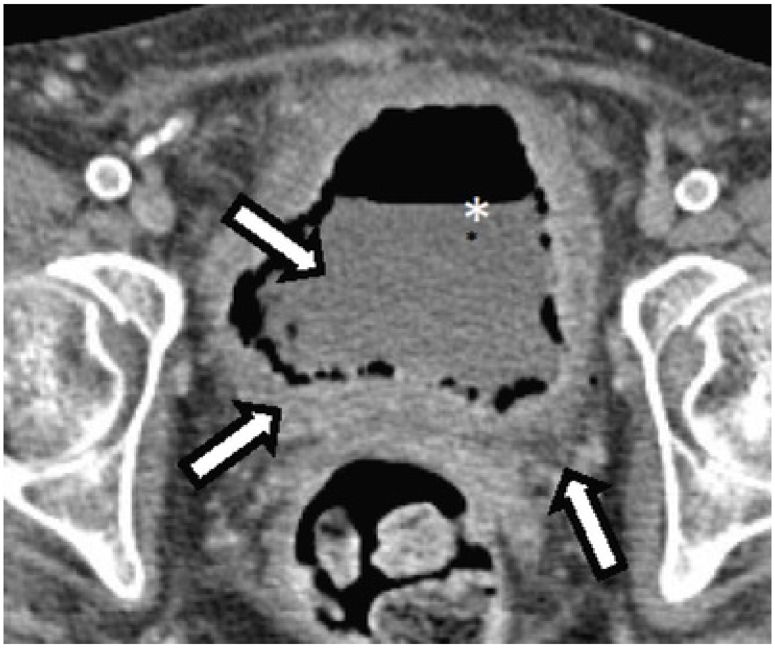


FIG. 55.14 Computed tomography of emphysematous cystitis. *Arrows* indicate intramural gas; there is also air in the bladder lumen (*).

Management.

The majority (90%) of these patients are treated with medical therapy alone, which consists of antibiotics (often parenteral), bladder drainage, and treatment of comorbid conditions such as poorly controlled diabetes (Amano and Shimizu, 2014). Antibiotic treatment regimens include agents that offer broad gram-negative coverage that can then be narrowed based on culture sensitivities and clinical response; if an initial Gram stain identifies gram-positive cocci, ampicillin or amoxicillin should be incorporated into the treatment regimen for better enterococcal coverage. The need for surgical intervention is rare and is reserved for those cases that respond poorly to initial medical management or severe necrotizing infections. The severity of the condition determines the nature of the surgical intervention, but case reports have described debridement, partial cystectomy, and total cystectomy in advanced cases (Thomas et al., 2007).

Unresolved Urinary Tract Infections

Clinical Presentation

Unresolved infection indicates that initial therapy has been inadequate in eliminating symptoms and/or pathologic bacterial growth in the urinary tract. If the symptoms of UTI do not resolve by the end of treatment or if symptoms recur shortly after therapy, a urinalysis and urine culture with susceptibility testing should be obtained. If the patient's symptoms are significant and cannot be alleviated with urinary analgesics, broad-spectrum antibiotics may be initiated as empirical therapy pending the availability of the culture and susceptibility testing.

The causes of unresolved bacteriuria during antimicrobial therapy are shown in Box 55.10. **Most commonly, the bacteria are resistant to the antimicrobial agent selected to treat the infection.** Typically, the patient has received the antimicrobial therapy in the recent past and developed bowel colonization with resistant bacteria. β-lactams, tetracycline, and sulfonamides are notorious for causing plasmid-mediated R factors that simultaneously carry resistance to multiple antimicrobial agents. **The second most common cause is development of resistance in a previously susceptible population of bacteria during the course of treatment of UTIs. This problem occurs in approximately 5% of the patients receiving antimicrobial therapy. It is easy to recognize clinically because the culture on therapy shows that the previous susceptible population has been replaced by resistant bacteria of the same species.** It can be shown that resistant organisms were actually present before contact with the initial antimicrobial agent, but they were present in such low numbers that it was impossible to detect by in vitro susceptibility studies before therapy. When the antimicrobial concentration in the urine is insufficient to kill all the bacteria present, the more resistant forms will emerge. This characteristically is seen in patients who are underdosed or who are poorly compliant and hence have inadequate dose regimens. **The third cause is the presence of an unsuspected, second pathogen that was present initially and is resistant to the antimicrobial therapy chosen.** Treatment of the dominant organism unmasks the presence of the second strain. **The fourth cause is rapid reintroduction of a new resistant species while the patient is undergoing initial therapy.** Rapid reinfection that mimics unresolved bacteriuria should alert the clinician to the possibility of an enterovesical fistula.

Box 55.10

Causes of Unresolved Bacteriuria, in Descending Order of Importance

Bacterial resistance to the drug selected for treatment
Development of resistance from initially susceptible bacteria
Bacteriuria caused by two different bacterial species with mutually exclusive susceptibilities
Rapid reinfection with a new, resistant species during initial therapy for the original susceptible organism
Azotemia
Papillary necrosis from analgesic abuse
Giant staghorn calculi in which the “critical mass” of susceptible bacteria is too great for antimicrobial inhibition
Self-inflicted infections or deception in taking antimicrobial drugs (a variant of Munchausen syndrome)

If the culture obtained on therapy shows that the initial species is still present and susceptible to the antimicrobial chosen to treat the infection, the unresolved infection must be caused by inability to deliver an adequate concentration of antimicrobial agents into the urinary tract, an excessive number of bacteria that “override” the antimicrobial activity, or noncompliance with the regimen. In patients with azotemia, a determination of urinary antimicrobial concentrations usually shows that the level of the drug is below the minimal inhibitory concentration of the infecting organism.

In patients with papillary necrosis, severe defects in the medullary concentrating ability dilute the antimicrobial agent. A large mass of bacteria within the urinary tract is most commonly associated with a giant staghorn calculus. Even though adequate urinary levels of bactericidal drugs are present, the concentration is inadequate to sterilize the urine. This occurs because even susceptible bacteria cannot be inhibited once they reach a certain critical density, particularly if attached to a foreign body.

The last cause of unresolved bacteriuria occurs in those patients who have variants of Munchausen syndrome. These patients secretly inoculate their bladders with uropathogens or omit their oral antimicrobial agents while steadfastly asserting that they never miss a dose. The patient with Munchausen syndrome has an inconsistent clinical history and invariably a normal urinary tract on urologic imaging. Careful bacteriologic observations usually indicate the implausibility of the clinical picture.

Laboratory Diagnosis

Urinalysis and urine culture are mandatory to determine the cause of unresolved bacteriuria. The first four causes associated with resistant bacteria require no further evaluation. However, if reculture shows that the bacteria are sensitive to the antimicrobial agent the patient is taking, renal function and radiologic evaluation should be performed to identify renal or urinary tract abnormalities.

Management

If the patient's symptoms are significant, initial broad-spectrum empirical antimicrobial treatment may be initiated, and selection should be based on the assumption that the bacteria are resistant. Therefore an antimicrobial agent different from the original agent should be selected.

Recurrent Urinary Tract Infections

A recurrent UTI is defined as two UTIs in a 6-month period or three or more UTIs in a 12-month period. Recurrent UTIs are common in otherwise healthy women. Indeed, in healthy college-age women, 20% had at least one culture-documented UTI within 6 months of an index UTI (Foxman et al., 2000). Other studies have reported a 20% to 30% recurrence rate in women (Albert et al., 2004; Gupta et al., 2001a,b). It is well established that one of the most significant risk factors for development of a UTI is a prior recent UTI. Recurrent infections are hypothesized to be secondary to either bacterial persistence within the urinary tract or, more commonly, novel reinfection. Persistence, caused by the same bacterial strain, usually leads to recurrent infections in a short time frame, whereas reinfections generally occur over a more remote period. Reinfections are caused by either the same organism more than 2 weeks after treatment or a different organism. Reinfection is likely secondary to ascent of uropathogens from fecal flora into the urinary tract or from reemergence of bacteria from uroepithelial intracellular colonies. In men, reinfections raise suspicion for the presence of anatomic abnormalities.

Evaluation

In evaluation of a woman with recurrent UTIs, the clinical focus should be on preventing recurrence by identifying risk factors for, and altering behaviors that contribute to, recurrent infections. The history and physical exam should eliminate overt external anatomic or obvious functional abnormalities of the urinary tract that predispose to recurrent UTIs. If any of these factors are identified, the UTIs are classified as complicated.

Obtaining a thorough medical history is imperative. Emphasis should be on ascertaining the prior number of infections and their frequency, culture results, associated symptoms, and identifiable triggers or risk factors. Symptoms such as pneumaturia, fecaluria, obstipation, as well as prior history of diverticulitis, prior pelvic surgery, or radiation should raise suspicion for vesicoenteric or vesicovaginal fistula. Description of any concomitant bowel symptoms, such as chronic constipation, diarrhea, and fecal incontinence may provide additional information to identify reversible contributing factors. Prior treatment strategies and patient response should be carefully investigated. **Significant risk factors for recurrence in women include sexual activity, a new sexual partner within the past year, menopause, spermicidal use, family history of UTI in a first-degree female relative, and recent antimicrobial use** (Dielubanza and Schaeffer, 2011; Hooton et al., 1996; Scholes et al., 2000, 2010). **In postmenopausal women, risk factors for recurrent UTIs include incontinence, elevated postvoid residual, and presence of a cystocele. A history of a UTI before menopause has also been identified as a risk factor** (Raz et al., 2000) (Box 55.11).

Box 55.11

Risk Factors for Recurrent Urinary Tract Infections

- Sexual activity
- New sexual partner within past year
- Family history of urinary tract infection (UTI) in first-degree female relative
- Recent antimicrobial use
- Spermicide use
- History of UTI before menopause
- Menopause
- Incontinence, elevated postvoid residual, cystocele (in postmenopausal women)

On physical examination, palpating the suprapubic area and performing a pelvic examination are important. One may identify a distended bladder; a significant postvoid residual contributes to bacteriuria. On pelvic examination the appearance of vaginal epithelium, particularly in postmenopausal women, should be characterized. The presence of pelvic organ prolapse or a urethral diverticulum could help establish the cause of recurrent UTIs.

Obtaining laboratory data, specifically urinalysis and urine culture, is imperative in patients with recurrent UTIs. Many of these patients are treated based on symptoms that overlap significantly with irritative storage symptoms and may in fact be inappropriately treated for UTIs. It is important in this population to establish that their symptoms are secondary to bacteriuria. In addition, quantification of the bacterial burden, species, and degree of resistance, if present, is also important information. Obtaining a urine culture in women with uncomplicated recurrent UTIs resulted in decreased hospitalization for treatment of UTI and decreased intravenous antibiotic usage (Suskind et al., 2016).

In many patients obtaining a postvoid residual and uroflow measurement provides important information. **In patients with emptying symptoms or a distended bladder on physical examination, documentation of a postvoid residual is critical.** In postmenopausal women with recurrent UTIs, higher postvoid residual and decreased urine flow were associated with uncomplicated recurrent UTIs (Raz et al., 2000). In fact, elevated PVR or decreased flow rates are often considered parameters that contribute to complicated UTIs; thus identification of abnormal values is important if the suspicion is high.

Imaging and cystoscopic evaluation are not warranted in all women with recurrent UTIs. Indeed, the yield of imaging in women without suspected complicated UTI is low and is not recommended by the American College of Radiology, the Canadian Urological Association Guidelines, or the European Association of Urology (EAU) Guidelines (Dason et al., 2011; EAU Guidelines, 2015; Segal et al., 2000). However, **in women with risk factors for a complicated UTI the evaluation should include imaging and cystoscopy.** These diagnostic tests may reveal kidney or bladder stones, neoplasms, fistulae, anatomic renal anomalies including scarring or papillary necrosis, or many other possible abnormalities (Table 55.9). Preferred imaging includes renal and bladder ultrasound with possible plain radiograph of the abdomen. In some cases, a CT scan is recommended as well, especially if there is a high index of suspicion for a complicated infection with no abnormality demonstrated on prior imaging. In patients with stones or obstruction, a CT scan is particularly useful in providing structural detail. In premenopausal women with a functional uterus, it is imperative to ask whether they may be pregnant; if they are uncertain, a pregnancy test should be obtained before any imaging that confers radiation (Fairchild et al., 1982).

TABLE 55.9

Indications for Further Investigation of Recurrent Urinary Tract Infection

Previous urinary tract trauma or surgery
Previous bladder or renal calculi
Gross hematuria after resolution of infection
Obstructive symptoms, low uroflowmetry, or high postvoid residual
Urea-splitting bacteria on culture
Previous abdominopelvic malignancy
Bacterial persistence after sensitivity-based therapy
Diabetes or other immune compromise
Pneumaturia, fecaluria, anaerobic bacteria, or history of diverticulitis
Repeated pyelonephritis
Asymptomatic microhematuria after resolution of infection should be evaluated

Data from Dason S, Dason J, Kappor A, et al.: Guidelines for the diagnosis and management of recurrent urinary tract infections in women. *Can Urol Assoc J* 5(5):316–322, 2011.

Many providers perform cystoscopy for the evaluation of all women with recurrent UTIs; however, several studies substantiate the fact that cystoscopy does not confer any added value beyond imaging, particularly in uncomplicated UTIs (Lawrentschuk et al., 2006; Pagano et al., 2017; van Haarst et al., 2001). These data demonstrate that, if imaging has been performed, an invasive diagnostic procedure should not be considered in the uncomplicated setting. There is utility for cystoscopic evaluation in patients with complicated UTIs.

Bacterial Persistence

For culture-documented infections with acute symptoms, if patients fail to respond to an appropriate course of antibiotics, then bacterial persistence may be present. **The incidence of bacterial persistence in the recurrent UTI population is very small, but, when present, it is critical to diagnose the source of persistence. In such cases of bacterial persistence, cystoscopic evaluation and imaging studies are necessary.** With persistence there are usually correctable urologic abnormalities that may be reversible (see Box 55.6). Such abnormalities create persistence often immune from treatment because of the inability of antibiotics to penetrate or eliminate the nidus of infection. In select instances, surgical removal of the source of infection has been shown to eradicate the infections (Stamey, 1980).

Proper evaluation for bacterial persistence includes endoscopic evaluation of the urinary tract as well as radiologic studies. Cystoscopy, ultrasonography, and CT scan may be useful in identifying the source. VCUG is useful when there is suspicion of VUR or the presence of a nonrefluxing ureteral stump. Pelvic MRI is standard of care to identify a urethral diverticulum. Retrograde urethrogram should be considered in men with suspected urethral stricture disease.

One of the most common causes of bacterial persistence are struvite renal calculi. Urea-splitting organisms, such as *P. mirabilis*, contribute to such infection stones (see Chapter 91, Table 91.3). Urease-splitting organisms cause alkalinization of urine with precipitation of calcium, magnesium, ammonium, and phosphate salts. These minerals contribute to formation of branched struvite stones. The bacteria in these stones often persist despite antibiotic treatment; urine cultures may show no growth after treatment, but this is misleading because the bacteria remain sheltered within these stones. Oxalate and apatite stones that become secondarily colonized also may contribute to bacterial persistence. Risk factors for the development of infection stones include chronic indwelling catheters, urinary diversions, or other urinary tract abnormalities that affect stasis. To eradicate bacteriuria thought to be related to stone disease, surgical treatment of the infection stones is recommended in all patients safe for intervention, per the AUA Guidelines: Medical Management of Kidney Stones (American Urological Association, 2014). In those patients with residual or recurrent struvite stones who are not surgical candidates, acetohydroxamic acid in conjunction with antibiotic suppression may be offered (American Urological Association, 2014).

Management of nonobstructing stones in recurrent UTIs is controversial. One study identified certain patient characteristics that increase the likelihood of recurrent UTIs despite complete stone extraction, including type 2 diabetes mellitus, hypertension, and black ethnicity (Omar et al., 2015). In this cohort of 120 patients 50% remained infection free 1 year after surgical extraction of the stone. Further research is necessary to determine whether eradicating small, nonobstructing stones has a beneficial effect on reducing the incidence of recurrent UTIs.

Management

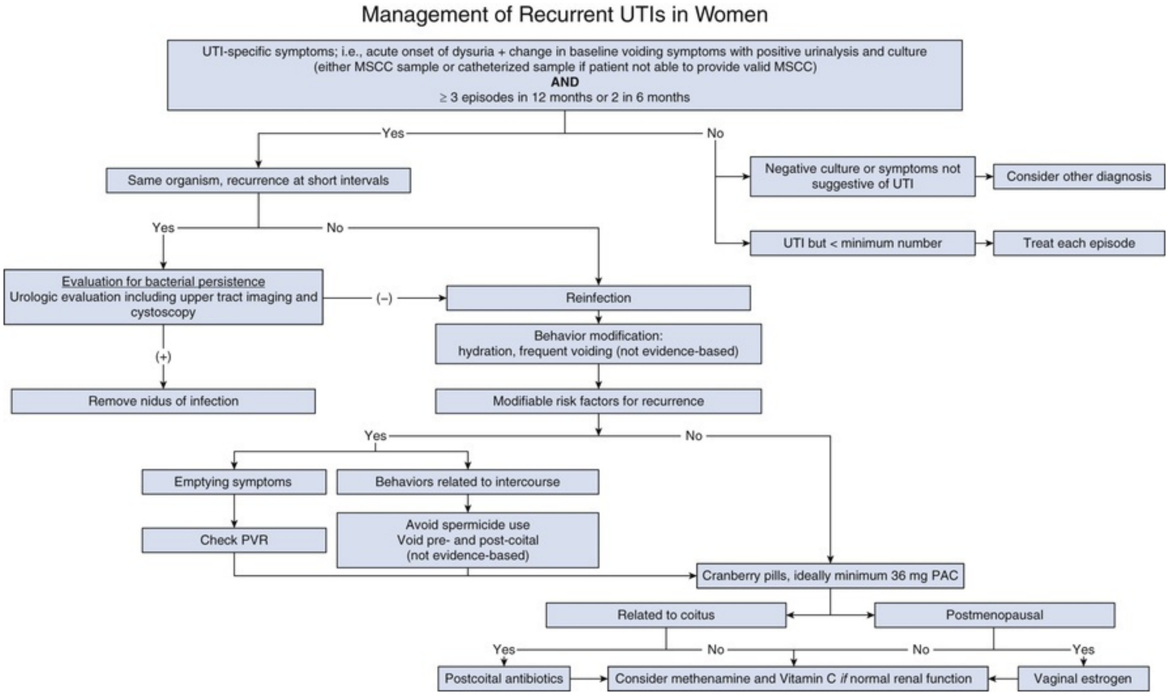
The majority of women with recurrent infections do not have identifiable and/or correctible anatomic abnormalities. Options for minimizing recurrent infections include behavioral modifications, use of non-antibiotic therapies, and, as a last resort, antibiotic treatment and prophylaxis.

In this era of widespread antibiotic overuse and the prevalence of alarming numbers of multidrug-resistant bacteria, judicious use of antibiotics is imperative.

The development of multidrug-resistant bacteria is associated with increased and prolonged hospitalization rates and significant adverse effects, including death. The Centers for Disease Control and Prevention (CDC) has reported that antibiotic resistance is one of the most serious health threats we encounter. More than 2 million people annually are infected with an antibiotic-resistant infection, which results in more than 20,000 deaths (CDC, 2014).

To minimize overuse of antibiotics and preserve their effectiveness, antibiotic stewardship programs have been developed. These programs have been efficacious at improving antibiotic prescribing patterns, improving patient outcomes, decreasing adverse effects, and improving rates of susceptibilities to particular agents (Barlam et al., 2016)**. Indeed, a recent Cochrane review demonstrated that stewardship programs have**

improved compliance with antibiotic guideline recommendations and have helped decrease the duration of antibiotic courses (Davey et al., 2017). The management of UTIs must adhere to antibiotic stewardship efforts (Fig. 55.15).



Management of Recurrent UTIs in Women
UTI-specific symptoms; i.e., acute onset of dysuria + change in baseline voiding symptoms with positive urinalysis and culture (either MSCC sample or catheterized sample if patient not able to provide valid MSCC) AND ≥ 3 episodes in 12 months or 2 in 6 months
Yes
No
Same organism, recurrence at short intervals
Negative culture or symptoms not suggestive of UTI
Consider other diagnosis
Yes
No
UTI but < minimum number
Treat each episode
Evaluation for bacterial persistence
Urologic evaluation including upper tract imaging and cystoscopy
(–)
Reinfection
Behavior modification: hydration, frequent voiding (not evidence-based)
(+)
Remove nidus of infection
Modifiable risk factors for recurrence
Yes
No
Emptying symptoms
Behaviors related to intercourse
Check PVR
Avoid spermicide use
Void pre- and post-coital
(not evidence-based)
Cranberry pills, ideally minimum 36 mg PAC
Related to coitus
Postmenopausal
Yes
No
No
Yes
Postcoital antibiotics
Consider methenamine and Vitamin C *if* normal renal function
Vaginal estrogen

FIG. 55.15 Algorithm for management of recurrent urinary tract infections. *MSCC,* Midstream clean-catch sample; *PAC,* proanthocyanidin; *PVR,* postvoid residual; *UTI,* urinary tract infection.

Behavioral Modification.

It is a clinically accepted principle that employing behavioral modification is a reasonable strategy to minimize recurrent UTIs, despite the lack of scientific evidence in support of several aspects of this approach. Such behavioral modifications carry minimal to no risks and enhance overall bladder health. Many women prone to UTIs acknowledge that they drink insufficient quantities of water and/or have a tendency to hold urine for extended periods despite feeling urges to void. Hydration is recommended to augment innate immunity by sloughing of urothelial cells and flushing of adherent bacteria. A recent study found that in premenopausal women with a history of recurrent UTIs, increasing water intake by 1.5 L daily led to a significant decrease in the number of cystitis episodes (Hooton et al., 2018). Likewise, frequent voiding helps to continually empty the bladder, which is particularly important if women have a tendency to hold urine for extended periods or do not empty their bladders adequately when they do void. Sexual activity is a known risk factor for UTIs because it transiently increases bacteriuria. Therefore emptying the bladder after intercourse should help minimize the likelihood that the transient bacteriuria will progress to clinical symptomatology of a UTI. By this same logic that has been favored for managing patients with a history of UTIs, voiding pre-intercourse, when possible, may also be beneficial. Spermicides (nonoxynol-9) have been associated with an increased risk of developing a UTI because they contribute to decreased population of normal vaginal flora and subsequently alter the vaginal pH, making the environment more hospitable for uropathogenic bacteria to thrive (Fihn et al., 1985,1996; Handley et al., 2002). Clinicians have speculated that shaving pubic hair and wearing thong underwear may contribute to recurrent UTIs; however, scientific data confirming this do not exist.

Self-Start Therapy.

One widespread practice that has been favored for managing patients who suspect they have a UTI involves allowing reliable patients to start antimicrobial therapy with onset of their typical UTI symptoms, sometimes without providing a urine sample or consulting their health care provider. Although this practice empowers the appropriate patient with the ability to self-diagnose and allows for instant access to antibiotics, it countermands the principles of antibiotic stewardship and the meaningful use of culture-specific antibiotics described in previous sections. Historical literature provided justification of this practice, with older studies suggesting patients have excellent diagnostic skills and will appropriately treat only when necessary (Gupta et al., 2001a,b; Schaeffer and Stuppy, 1999). Initially this approach depended on patients providing urine samples and following up for culture results after initiating antimicrobial therapy. With time, however, the expectation of providing samples has dissipated, and, in the current era, most patients begin antibiotics without making an effort to confirm the presence of a UTI, much less the causative organism and sensitivities.

Historically, patients were encouraged to rely on broad-spectrum antibiotics to treat their symptoms, and fluoroquinolones were considered “ideal” agents for self-start therapy. However, although this approach is endorsed by many practitioners, partially because of ease of patient management, this strategy only perpetuates antibiotic overuse by relying on self-diagnosis. Many patients with a history of UTIs have anxiety because of fear of when the next UTI will appear. These patients may prematurely and incorrectly initiate treatment if they notice any change in their typical urinary habits; often patients are quick to assume they have another UTI if they have a slight increase in urgency, or mild discomfort with urination. **Our anecdotal clinical experience suggests that patients are not always adequate diagnosticians when it comes to UTIs, and the risks outweigh the benefits of self-start therapy. A practice that allows patients to self-medicate, often with extended courses of broad-spectrum antibiotics, is not a sustainable strategy.**

In the management algorithm for recurrent infections, many experienced clinicians encourage patients to medicate with urinary analgesics with the onset of symptoms to provide some relief, provide a urine sample, and continue observation unless they display significant symptoms. For persistent issues despite analgesics, prescription of IDSA-recommended antibiotics, in consultation with local antibiograms, may be administered and tailored once culture results are available. In many cases patient symptoms are transient and unrelated to bacterial infection and thus are self-limiting; this approach spares a course of unnecessary antibiotics.

Low-Dose Continuous Prophylaxis.

Another widely advocated management option for recurrent UTIs is daily prophylaxis with low-dose antibiotics. Conceptually, this strategy has been promoted because particular antimicrobial agents eradicate pathogenic bacteria from introital and bowel reservoirs without fostering bacterial resistance. Many papers were published in the late 20th century endorsing the use of TMP-SMX, TMP alone, nitrofurantoin, cephalexin (low dose) and fluoroquinolones, as well as several other antibiotics no longer in use (Bailey et al., 1971; Martinez et al., 1985; Nicolle, et al., 1989; Raz and Boger, 1991; Stamm et al., 1980a). In these studies, some of which were placebo controlled, patients who received daily prophylaxis, generally for 6 months to a year, demonstrated lower rates of UTIs (compared with placebo or with the patients’ prior experiences as controls). Although these studies concluded that daily antibiotic use was safe and effective, some did mention an increased incidence of non-*E.coli* UTIs after such prophylaxis.

A 2004 Cochrane review of AP against recurrent UTIs in non-pregnant women concluded that women with uncomplicated recurrent UTIs are less likely to have an infection if they take prophylactic antibiotics for 6 to 12

months (Albert et al., 2004). This review included 19 randomized controlled studies, involving 1120 women. Study designs of these 19 studies included comparing antibiotics with placebo, the same antibiotic with different regimens (i.e., daily vs. weekly vs. monthly vs. postcoital), different antibiotics, or antibiotics versus non-antibiotic pharmacologic interventions. The majority of these studies evaluated 6 months of prophylaxis; only one studied subjects for 1 year of treatment. The most recently published study included was published in 1995. The studies reported on the number of recurrences while subjects were on prophylaxis as well as after prophylaxis was discontinued. Adverse effects of antibiotic use were also investigated. The authors concluded that continuous antibiotic use did decrease the clinical and microbiologic recurrence rate; however, there were more adverse effects attributed to the antibiotics.

Only two studies performed follow-up 6 months beyond the prophylactic period (Schaeffer et al., 1982; Stamm et al., 1980). In these two studies, once prophylaxis was discontinued, the recurrence rate was comparable between those treated and the placebo group. Therefore, **although prophylaxis was deemed an effective strategy in the short term, in the long term patients who were treated prophylactically demonstrated the same risk of recurrence as those not treated.** Two of the studies assessed postcoital antibiotic use; one compared it with placebo, the other compared it with daily antibiotics use. Both studies found that postcoital antibiotic use, in women with recurrent UTIs secondary to intercourse, is an effective strategy and is preferable to daily antibiotic use.

Although many practitioners advocate prophylactic antibiotics, at least in part because of the conclusions of this Cochrane review, several points must be emphasized. The authors of the Cochrane review questioned the quality of the clinical trials reviewed, specifically citing concerns regarding inconsistent definitions of recurrent UTIs, outcomes analyzed, analysis of antibiotic side effects, and follow-up of subjects. Although continuous antibiotics were effective, no consensus existed related to how long to continue suppression. The studies analyzed in this review are several decades old, performed at a time when antibiotic resistance rates were much lower than those encountered today. Clearly long-term suppressive antibiotics pose a major risk to society because this practice undoubtedly will contribute to perpetuation of multidrug-resistant organisms. **Because of the risk of adverse effects of exposure to antibiotics, long-term treatment with daily prophylaxis is not an appropriate contemporary approach. Indeed, the European Association of Urology (EAU) guidelines for urologic infections state that recent concerns highlight**

the “need for reconsidering long-term antibiotic prophylaxis in recurrent UTI and assess in each individual case effective alternative preventive measures” (Grabe et al., 2015). If patients desire indefinite daily prophylaxis they should be educated that no long-term data exist in support of this strategy and that they are exposing themselves to potentially severe side effects and development of multidrug-resistant organisms.

Postcoital antibiotic use is an acceptable strategy in patients with a clear-cut causal relationship between intercourse and onset of UTIs when other management options have not been effective. Ideally, prior cultures with sensitivities should be taken into consideration when choosing an antibiotic, in addition to a patient's allergies as well as local resistance patterns and ecologic effects of the chosen agent.

Nitrofurantoin remains a popular choice for prophylaxis because it concentrates in urine, is efficacious against many uropathogens, and does not promote widespread resistance. However, nitrofurantoin is associated with significant adverse effects, particularly with long-term use. Unfortunately, providers do not routinely address the risk of pulmonary fibrosis or renal and neurotoxicity, and many patients are encouraged to take it daily, indefinitely, lacking appropriate counseling detailing the potential harm they may encounter in the future. A recent systematic review and meta-analysis of common antibiotics used for prophylaxis in women concluded that nitrofurantoin was equally as effective, in terms of clinical and microbiologic cure, as norfloxacin, trimethoprim, sulfamethoxazole/trimethoprim, cefaclor, estriol, or methenamine hippurate. However, it was also associated with increased risk of adverse effects, mostly related to the GI tract (Price et al., 2016).

Non-Antibiotic Management.

Although it has been historically acceptable to recommend AP, a review of the literature from the last 10 years suggests that the majority of recent research has focused on non-antibiotic strategies to prevent UTIs. Contemporary research corroborates that, although AP may be effective, increasing rates of antibiotic resistance and subsequent adverse ecologic effects associated with AP make this strategy less desirable. **It is imperative that we develop alternatives to antibiotics for minimizing UTIs without further contributing to the alarming rates of antibiotic resistance; as stated earlier more than two million illnesses and more than 20,000 deaths occur yearly because of antibiotic resistance.**

Recent articles have reviewed several forms of non-AP; one included a systematic review and meta-analysis of available randomized controlled trials (RCTs). The authors found that the oral immunostimulant OM-89, the vaginal vaccine Urovac, vaginal estrogen, cranberry, and acupuncture had varying degrees of success in lowering the risk of recurrent UTIs; however, oral estrogens and lactobacilli were not effective (Beerepoot et al., 2013). Another review article examined the efficacy of vitamin C, cranberry, estrogen, lactobacilli, methenamine, OM-89, and Urovac (Geerlings et al., 2014). Use of vitamin C was not deemed effective in reducing the incidence of UTIs, whereas the others had varying degrees of success. Researchers acknowledge that further studies must be undertaken, particularly comparisons between specific products and the gold-standard AP, before strong recommendations can be made in support of non-antibiotic strategies. In addition, standardized doses and products should be used in all studies to make the conclusions more powerful.

Cranberry.

Cranberry products for UTI prophylaxis have been investigated for years in the scientific and lay press. **One of the active ingredients in cranberry is the polyphenol type A proanthocyanidin (PAC), which prevents the P fimbriae of *E. coli* from adhering to uroepithelial cells** (Howell et al., 2010). Studies have investigated various formulations of cranberry, including juice/concentrate, capsules, tablets and extract, in comparison with placebo or no treatment (Barbosa-Cesnik et al., 2011; Kontiokari et al., 2001; Stothers, 2002). Other studies have examined the efficacy of cranberry versus AP (Beerepoot et al., 2011; McMurdo et al., 2009).

Some of the earlier studies were analyzed in a **Cochrane review from 2008** (Jepson and Craig, 2008). This review included 10 studies (1049 subjects) that investigated cranberry supplementation in patients with recurrent UTIs. Most of these studies (seven) evaluated use of juice, whereas tablet formulations were evaluated in four studies. One study investigated juice and tablets. Investigators concluded that cranberry was effective in reducing the incidence of recurrent UTIs in women as compared with older men or women, or people who required catheterization (either indwelling catheters or who performed CIC). Indeed, **in women with recurrent UTIs cranberry significantly reduced the incidence of UTIs at 1 year** (RR 0.65; 95% CI 0.46–0.90). As discussed by investigators who conducted this review, an obstacle in drawing conclusions about the efficacy of cranberry is that there was significant heterogeneity of products available and routes of administration, thus making the dosage of cranberry in each study population variable. Although side effects were minimal, there was a large dropout rate, particularly in those who ingested the juice.

A more recent Cochrane review added 14 more studies to the original review; thus a total of 24 studies (4473 subjects) were included (Jepson et al., 2012). In these investigations various cranberry formulations were evaluated and compared with placebo, water, antibiotics, methenamine, lactobacillus, or no treatment. In contrast to the earlier meta-analysis, these data reported that cranberry supplementation did not significantly reduce the symptomatic UTI rate overall, in comparison with water, placebo, or no treatment (RR 0.86; 95% CI 0.71–1.04). **In subgroup analysis, cranberry did not significantly reduce the recurrence rate of UTIs in any group, including in women with a history of recurrent UTIs (RR 0.74; 95% CI 0.42–1.31), a contradictory finding compared with the prior Cochrane review**. Interestingly, two of the studies compared cranberry capsules or syrup with AP in women with recurrent UTIs and found that cranberry was equally as effective as antibiotic in reducing the risk of recurrent UTIs (RR 1.31; 95% CI 0.85–2.02).

Although GI adverse effects were no higher in those who took cranberry products compared with placebo or no treatment, many studies did report low compliance rates/high dropout rates, which were attributed to tolerability of the products, particularly juice intake. **The authors of the review did acknowledge that most studies did not report on how much active ingredient, or PAC, the products had, and thus the products may not have been potent enough to achieve desired results**. **Based on this more recent review, cranberry juice cannot be recommended for prevention of recurrent UTIs; however, the efficacy of other cranberry products must be further examined and must include standardization of the preparation and confirmation of the presence of active ingredient. Based on prior research, 36 mg of PAC equivalents/day has been shown to be effective, but 72 mg may be even more effective** (Howell et al., 2010; Fig. 55.16). In addition, because the anti-adhesion effect is not long acting, the product should be taken twice a day.

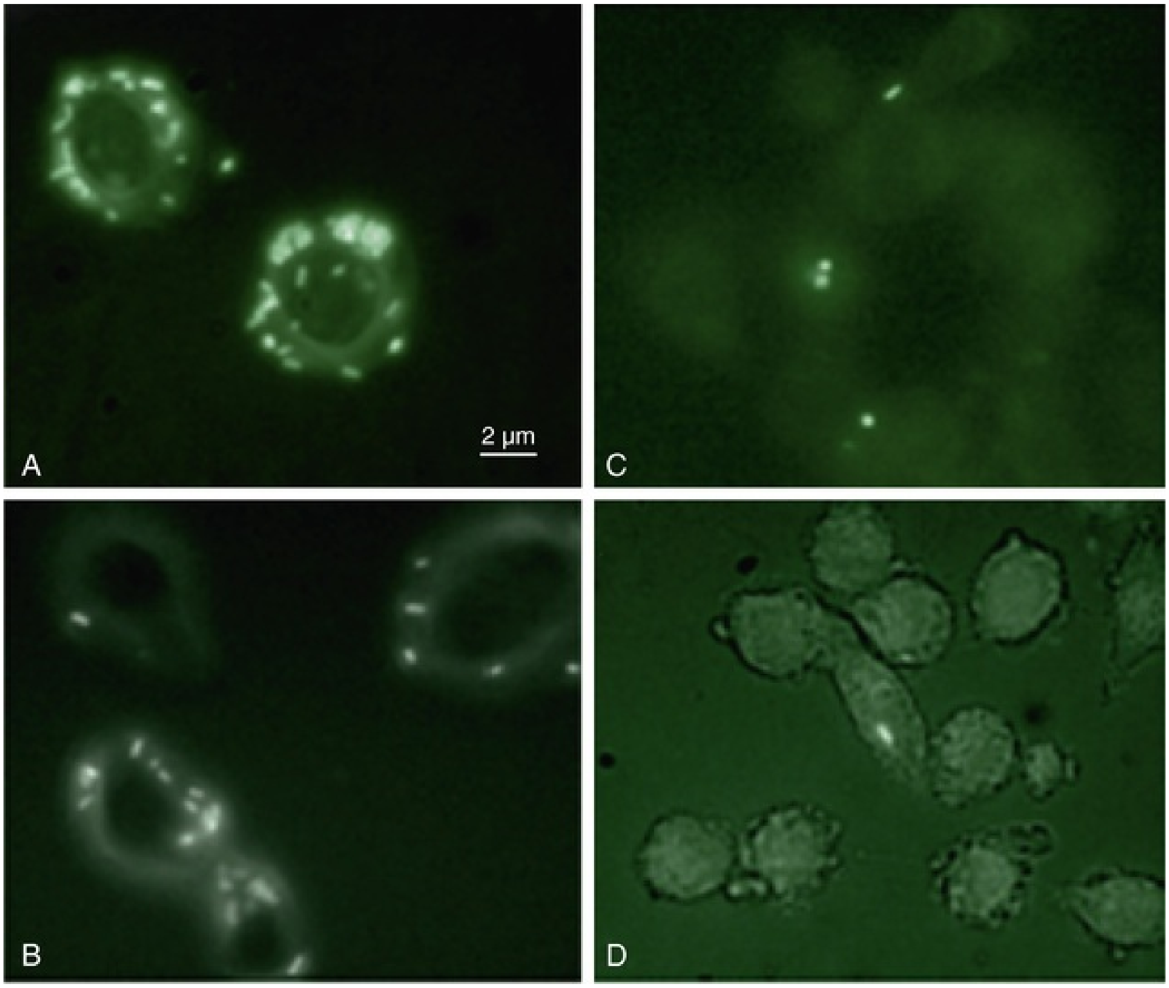


FIG. 55.16 *Escherichia coli* and effect of proanthocyanidin (PAC). (A) *E. coli* cultured in urines collected after placebo consumption. (B) *E. coli* cultured in urines collected 6 hours after consumption of cranberry powder containing 18-mg PAC. (C) *E. coli* cultured in urines collected 6 hours after consumption of cranberry powder containing 36-mg PAC. (D) *E. coli* cultured in urines collected 6 hours after consumption of cranberry powder containing 72-mg PAC.

Administering 72 mg of PAC daily to women in nursing homes was ineffective in decreasing the rates of bacteriuria plus pyuria, or of developing a symptomatic UTI, over a 1-year period (Juthani-Mehta et al., 2016). However, the majority of these women did not have bacteriuria plus pyuria or recurrent symptomatic UTIs before the study period, so the benefit of PAC may not have been as apparent as it may have been in a different cohort, namely those who were prone to UTIs. In addition, samples were obtained via midstream clean-catch samples, rather than catheterized samples, despite that these women were most likely atrophic and may have had comorbidities that made providing appropriate voided samples more challenging. Furthermore, postvoid residual volumes or degree of incontinence were not characterized; these are two known risk factors for bacteriuria in the elderly population. Although this study had significant limitations, some argued that these data confirm that “it is time to move on from cranberries” (Nicolle, 2016). However, challenging the efficacy of cranberry in preventing recurrent UTIs in all women based on results from a nursing home cohort does not seem wise.

The most recent systematic review and meta-analysis of cranberry products included 28 studies (4947 subjects) and concluded that ingestion of cranberry products confer a significant reduction in the risk of recurrent UTIs (Luis et al., 2017). A subgroup analysis determined that subjects with a history of recurrent UTIs and those who had undergone gynecologic surgery benefitted the most from cranberry products.

Although research has determined that a minimum quantity of 36 mg of PAC is most important in achieving efficacy against recurrent UTIs, few products report on the PAC content. In addition the cost of those products that report on PAC dosage may make them prohibitively expensive for some.

A pre-existing FDA warning to avoid cranberries and cranberry products when taking warfarin was removed in 2011. The concern about adverse interactions, specifically that cranberry elevates the INR and thus increases bleeding diathesis, has not been substantiated in scientific studies (Ansell et al., 2009; Mellen et al., 2010; Zikria et al., 2010). **Practitioners should feel comfortable recommending cranberry products even if their patient is taking warfarin.**

As evidenced by the contradictory conclusions of the Cochrane reviews, as well as various other articles reviewed, the efficacy of cranberry supplements in minimizing recurrent UTIs is controversial at best and remains an area ripe for more investigation. The authors do recommend cranberry supplements, ideally those with a minimum of 36 mg of PAC, based on our successful anecdotal experience.

Estrogen.

Postmenopausal women may have frequent reinfections (Hooton and Stamm, 1991; Raz and Stamm, 1993). Such infections are **sometimes attributable to residual urine** after voiding, which is often associated with bladder or uterine prolapse. **In addition,** decreased estrogen levels contribute to the transformation to atrophic vaginal epithelium and increased vaginal pH, which creates a more hospitable environment for bacteria to thrive. Indeed, **the lack of estrogen**

causes marked changes in the vaginal microflora, including a loss of lactobacilli and increased colonization by *E. coli* (Raz and Stamm, 1993). An early placebo-controlled study with 93 women showed that the use of vaginal estriol reduced the number of UTIs as compared with placebo (RR 0.25; 95% CI 0.13–0.50) (Raz, 1993). The UTI rate was significantly lower in the group that received the vaginal estriol (0.5 vs. 5.9 episodes per patient-year, $P < 0.001$) (Fig. 55.17). The efficacy was attributed to the reemergence of vaginal lactobacilli and the decrease in vaginal pH in those who received vaginal estrogen. Adverse effects were minimal, although there was a 28% dropout rate in the estrogen group as compared with 17% in the placebo group; the most common reason for dropout was bothersome local adverse reactions to estriol including vaginal burning, itching, or irritation. Another study compared the use of an estradiol-releasing vaginal ring to no estrogen administration and found that the use of vaginal estrogen lowered the likelihood of developing a UTI in postmenopausal women with a history of recurrent UTIs (RR 0.64; 95% CI 0.47–0.86; Eriksen, 1999).

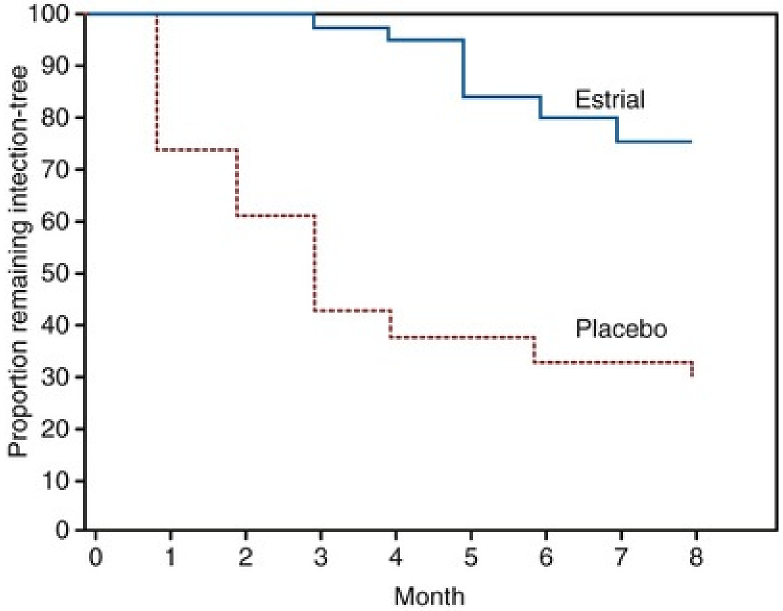

FIG. 55.17 Kaplan-Meier analysis showing the cumulative proportions of women remaining free of urinary tract infections in the Estriol and placebo groups ($P < 0.001$ by the Log-Rank Test). (Data from Raz R, Stamm WE: A controlled trial of intravaginal estriol in postmenopausal women with recurrent urinary tract infections, *N Engl J Med* 329(11):753–756, 1993.)

This literature was included in a **Cochrane review** that investigated the efficacy of oral and vaginal estrogen in preventing recurrent UTIs in postmenopausal women (Perrotta et al., 2008). A total of nine studies that included 3345 women were analyzed. Oral estrogens compared with placebo, analyzed in four studies, were not effective in preventing a UTI. Some of the studies comparing oral antibiotics to vaginal estrogen showed significant heterogeneity and results could not be pooled. Based on the two studies discussed earlier, the authors concluded that **vaginal estrogen is effective in preventing recurrent UTIs in postmenopausal women. The beneficial effect from vaginal estrogen use can take at least 12 weeks to manifest.** Adverse effects included breast tenderness, nonphysiologic discharge, and vaginal bleeding/spotting, irritation, itching and burning. Investigators encouraged the performance of future studies that investigated the optimal administration of vaginal estrogen.

A recent review of various forms of vaginal estrogen was performed and found that all forms (estrogen cream, tablets, and ring) improved symptoms of vaginal atrophy, but the impact on UTIs specifically was not analyzed (Lethaby et al., 2016).

Package inserts for vaginal estrogen preparations include warnings about potential systemic effects of estrogen administration, which likely contributes to some patients’ reluctance to initiate vaginal estrogen therapy. However, the boxed warnings refer to all forms of estrogen administration, regardless of route of administration, and concerns about the risks of *vaginal* estrogen have not been supported by scientific studies. Although estrogen is detectable in plasma after vaginal administration, the levels are lower compared with those achieved with oral administration of low-dose conjugated estrogens. Daily administration of low-dose vaginal estrogen resulted in steady-state estrogen concentrations that were noted to be within or slightly above the normal reference range for postmenopausal women (Dorr et al., 2010). Indeed, all low-dose vaginal estrogen preparations result in minimal systemic absorption that results in levels that do not exceed normal postmenopausal levels (Santen, 2015).

RCTs of vaginal estrogen use have not been designed to analyze outcomes such as cancer or cardiovascular disease. However, observational studies have found no increased risk of fracture or breast cancer in women who used vaginal estrogen (Lyytinen et al., 2006; Michaelsson et al., 2002). Analysis of data from subjects in the Women's Health Initiative Observational Study confirmed that vaginal estrogen preparations do not confer an increased risk of cancer or cardiovascular disease (Crandall et al., 2018).

Vaginal estrogen use in breast cancer survivors has been studied. An increased risk of breast cancer recurrence was not demonstrated (Dew et al., 2003; Le Ray et al., 2012), including in those who were taking tamoxifen. The safety of vaginal estrogen use in survivors who are taking aromatase inhibitors has not been clearly demonstrated (Wills et al., 2012). All of these studies focused on vaginal estrogen use for amelioration of symptoms secondary to vulvovaginal atrophy. Despite the lack of data demonstrating an increased risk of recurrence, vaginal estrogen use is generally discouraged in this population (Santen et al., 2017). However, for these women who are suffering from recurrent UTIs vaginal estrogen can be prescribed after endorsement from their oncologist. As discussed, data *do not* demonstrate an increased risk of cancer recurrence but *do* demonstrate a decreased risk of recurrent UTIs.

Laser therapy to treat symptoms associated with vulvovaginal atrophy has become popular in recent years as an alternative to hormonal therapies. The MonaLisa Touch laser is a fractional CO_2 laser designed for the vaginal mucosa. It stimulates the production of new collagen. Scientific data supporting this modality to decrease the risk of recurrent UTIs do not exist.

Probiotics.

Certain strains of lactobacilli can interfere with the presence of uropathogenic bacteria in the urogenital epithelium. The maintenance of normal urogenital flora may be enhanced by strains that produce antibacterial substances such as hydrogen peroxide (Falagas et al., 2006). Initial studies evaluated various strains for prevention of recurrent UTIs, including a *Lactobacillus* GC drink and the vaginal suppository *L. casei v rhamnosus* (Baerheim et al., 1994; Kontiokari et al., 2001). However, neither product proved effective in reducing the UTI recurrence rates. More recent studies using *L. crispatus* vaginal suppositories and *L. rhamnosus GR-1* and *L. reuteri RC-14* oral capsules showed more promising results (Beerepoot et al., 2012; Stapleton et al., 2011).

A Cochrane review published in 2015 examined the efficacy of probiotic use in women and children (Schwenger et al., 2015). This review included 9 studies; study design compared probiotics with placebo, no treatment, or antibiotics. Many forms and dosages of probiotics and duration of treatment were used in the studies reviewed. This review concluded that **probiotics cannot be recommended as an effective strategy for prevention of recurrent UTIs.** However, the authors acknowledge the studies reviewed were small and had design flaws. More investigation into the efficacy of probiotics is necessary before they become part of the urologist's treatment algorithm.

Methenamine.

Methenamine salts, which have been used for urinary indications for approximately 100 years, are 70% to 90% renally excreted and are converted to ammonia and formaldehyde in an acidic environment ($pH < 6$) (Lo et al., 2014). Formaldehyde is either bactericidal or bacteriostatic in urine depending on its concentration. To achieve acidification of the urine when these oral tablets are taken, high doses of ascorbic acid (vitamin C) (1–4 g) can be ingested in conjunction with the methenamine (recommended dose is 1 g twice daily). Two formulations of methenamine are FDA approved, methenamine hippurate and methenamine mandelate. Two early randomized placebo-controlled trials conducted in otherwise healthy women demonstrated a 56% to 75% reduction in recurrent UTIs with the use of methenamine mandelate 500 mg four times daily with ascorbic acid 500 mg four times daily, and methenamine hippurate 1 g twice daily without the addition of vitamin C (Cronberg et al., 1987; Harding, 1974). The acid salts, mandelate and hippurate, have nonspecific bacteriostatic properties and are therefore not effective against urease-producing bacteria. Methenamine is contraindicated if the creatinine clearance is less than 50 cc/min or in patients with severe liver disease or hypersensitivity to the drug or its components. It must also be avoided in patients who are also taking sulfonamides, antacids, and carbonic anhydrase inhibitors (Table 55.10).

TABLE 55.10

Methenamine Drug Interactions

Antacids: may diminish therapeutic effect
Carbonic anhydrase inhibitors: may diminish therapeutic effect
Sodium picosulfate: therapeutic effect may be diminished by concomitant methenamine use
Foods/diets that alkanize urine ($pH > 5.5$)[a]: may diminish therapeutic effect

[a] Almonds; chestnuts; flax, pumpkin, and sunflower seeds; berries; cherries; grapes; citrus; cantaloupe; figs; kiwi.

Data from Lo TS, Hammer KD, Zegarra M, Cho WC: Methenamine: a forgotten drug for preventing recurrent urinary tract infection in a multidrug resistance era. *Expert Rev Anti Infect Ther* 12(5):549–554, 2014.

A Cochrane Review published in 2012 included 13 studies (2032 subjects) of methenamine hippurate (Lee et al., 2012). Various doses were investigated in these studies, ranging from 1 to 4 g per day. Acidification agents were combined with methenamine in only two of the studies. Researchers concluded that there was significant heterogeneity in the studies reviewed; thus definitive conclusions could not be made. However, methenamine showed some benefit in patients with normal urinary tracts (symptomatic UTI: RR 0.24; 95% CI 0.07–0.89; bacteriuria: RR 0.56; 95% CI 0.37–0.83), but not in patients with anatomic abnormalities (symptomatic UTI: RR 1.54; 95% CI 0.38–6.20; bacteriuria: RR 1.29; 95% CI 0.54–3.07). **In patients who had normal urinary tracts and did not have indwelling catheters, short-term (≤7 days) therapy contributed to a significant reduction in symptomatic infections (RR 0.14; 95% CI 0.05–0.38).** Methenamine hippurate was not effective in patients with known urinary tract abnormalities. Adverse effects were infrequent; nausea and diarrhea were most frequently encountered.

Concern has been raised about the use of a product that gets converted to formaldehyde, which is listed as a carcinogen in the 2011 National Toxicology Program Report on Carcinogens. However, in this report, formaldehyde has been associated with nasopharyngeal cancer, sinonasal cancer, and lymphohematopoietic cancers. Formaldehyde was not listed as being associated with urothelial cancers. The risk of developing bladder cancer secondary to the use of methenamine thus appears to be theoretical (Geerlings et al., 2014).

D-Mannose.

D-mannose is a simple sugar that has shown some promise recently in preventing bacterial adhesion to the urothelium. It binds and blocks Fim H, an adhesin protein located at the tip of type 1 pili of enteric bacteria, therefore functioning as a competitive inhibitor of bacterial adhesion mechanisms. Historically it has been used for treating UTIs in some animals (Altarac and Papes, 2014). Recent studies have found that D-mannose was equally as efficacious as nitrofurantoin in reducing the risk of recurrent UTIs and demonstrated a significantly lower risk of adverse effects. D-mannose was also effective in reducing symptoms associated with acute cystitis as well as preventing recurrent UTIs (Domenici et al., 2016; Kranjcec et al., 2014). More studies must be performed to draw more definitive conclusions about the efficacy of D-mannose. Optimal dosing for D-mannose formulations remains unknown.

Immunoactive Prophylaxis.

Bacterial extracts have been investigated as potential prophylactic agents against UTIs. Oral and vaginal products exist and have been studied.

The oral immunostimulant OM-89 (Uro-Vaxum) is an extract that contains 18 serotypes of heat-killed uropathogenic *E. coli*. The different serotypes increase neutrophils and macrophage phagocytosis, thereby stimulating the host immune system to target uropathogenic *E. coli*. Several studies have investigated the efficacy of OM-89 in women with recurrent UTIs (Bauer et al., 2005; Magasi et al., 1994; Schulman et al., 1993; Tammen, 1990). A meta-analysis of these studies included 891 patients who took 1 capsule a day of OM-89 or placebo (Beerepoot et al., 2013). In the treated group the risk ratio of developing at least one UTI was significantly lower in the OM-89–treated group (RR 0.61; 95% CI 0.48–0.78). The mean number of UTIs was also about 50% lower in the treated group, as compared with placebo. Adverse effects were equally common in the treated and placebo groups, with headaches and GI complaints reported most frequently. The manufacturer of OM-89 funded some of the studies, so results must account for potential funding bias. A more recently conducted meta-analysis of existing studies of OM-89 identified 15 double-blind randomized controlled studies but only included 5 in their analysis because of methodologic flaws with the other 10 studies (Taha Neto et al., 2016). Although analysis of the literature demonstrated a benefit in favor of OM-89, the authors concluded that the studies were of variable quality, demonstrated potential reporting bias, and had short follow-up. They emphasized the need for future high-quality studies with longer follow-up before endorsement of OM-89 for use in prophylaxis is justified.

A vaginal vaccine (Urovac) that works via stimulating IgA and IgG in the urinary tract and subsequently decreasing potential colonization of uropathogens has also been studied (Hopkins et al., 2007). The vaccine contains 10 heat-killed uropathogenic bacterial species, including six serotypes of uropathogenic *E. coli, Proteus vulgaris, K. pneumoniae, Morganella morganii*, and *E. faecalis*. Three trials that included 220 women total were conducted by the same group of investigators. In one trial, primary immunization (three vaginal vaccine suppositories at weekly intervals) was compared with placebo (Uehling et al., 1997); in the other two trials booster immunizations (three additional suppositories at monthly intervals) followed initial primary immunization (Hopkins et al., 2007; Uehling et al., 2003). Women who received the boosters were less likely to develop a UTI. A meta-analysis of these three studies concluded that Urovac slightly reduced recurrent UTI rates (RR 0.81; 95% CI

0.68–0.96) (Beerepoot et al., 2013). More studies with much larger numbers of subjects must be conducted before robust conclusions can be made about Urovac.

In 2019 the AUA released a guideline on evaluation and management of recurrent uncomplicated UTIs in women (American Urological Association, 2019).

Key Points: Recurrent Urinary Tract Infections

- Obtaining a thorough history is critical, with emphasis on prior symptoms, urinalysis and culture results, and triggers for infections.
- Sources of possible bacterial persistence must be identified and eradicated.
- Imaging and cystoscopy are NOT recommended for recurrent uncomplicated UTIs.
- Prevention of recurrence should focus on nonantibiotic interventions.

Kidney Infections

Renal Infection (Bacterial Nephritis)

Although renal infection is less prevalent than bladder infection, it often is a more difficult problem for the patient and his or her physician because of its often varied and morbid presentation and course, the difficulty in establishing a firm microbiologic and pathologic diagnosis, and its potential for significantly impairing renal function. **Although the classic symptoms of acute onset of fever, chills, and flank pain are usually indicative of renal infection, some patients with these symptoms do not have renal infection. Conversely, significant renal infection may be associated with an insidious onset of nonspecific local or systemic symptoms, or it may be entirely asymptomatic.** Therefore a high clinical index of suspicion and appropriate radiologic and laboratory studies are required to establish the diagnosis of renal infection.

Unfortunately, **the relationship between laboratory findings and the presence of renal infection often is poor. Bacteriuria and pyuria, the hallmarks of UTI, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside of the collecting system.**

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Interstitial renal inflammation, once thought to be caused predominantly by bacterial infection, is now recognized as a nonspecific histopathologic change associated with a variety of immunologic, congenital, or chemical lesions that usually develop in the absence of bacterial infection. Infectious granulomatous diseases of the kidney often have either radiologic or pathologic characteristics that mimic renal cystic disease, neoplasia, or other renal inflammatory disease.

The effect of renal infection on renal function is varied. Acute or chronic pyelonephritis may transiently or permanently alter renal function, but nonobstructive pyelonephritis is no longer recognized as a major cause of renal failure (Baldassarre and Kaye, 1991; Fraser et al., 1995). However, pyelonephritis, when associated with urinary tract obstruction or granulomatous renal infection, may lead rapidly to significant inflammatory complications, renal failure, or even death.

Pathology

The opportunity for pathologic confirmation of **acute bacterial nephritis** is rare. The kidney may be edematous. Focal acute suppurative bacterial nephritis caused by hematogenous dissemination of bacteria to the renal cortex is characterized by multiple focal areas of suppuration on the surface of the kidney (Fig. 55.18). Histologic examination of the renal cortex shows focal suppurative destruction of glomeruli and tubules. Adjacent cortical structures and the medulla are not involved in the inflammatory reaction. **Acute ascending pyelonephritis** is characterized by linear bands of inflammation extending from the medulla to the renal capsule (Fig. 55.19). Histologic examination usually reveals a focal wedge-shaped area of acute interstitial inflammation with the apex of the wedge in the renal medulla. Polymorphonuclear leukocytes or a predominantly lymphocytic and plasma cell response are seen. Bacteria also may be present.

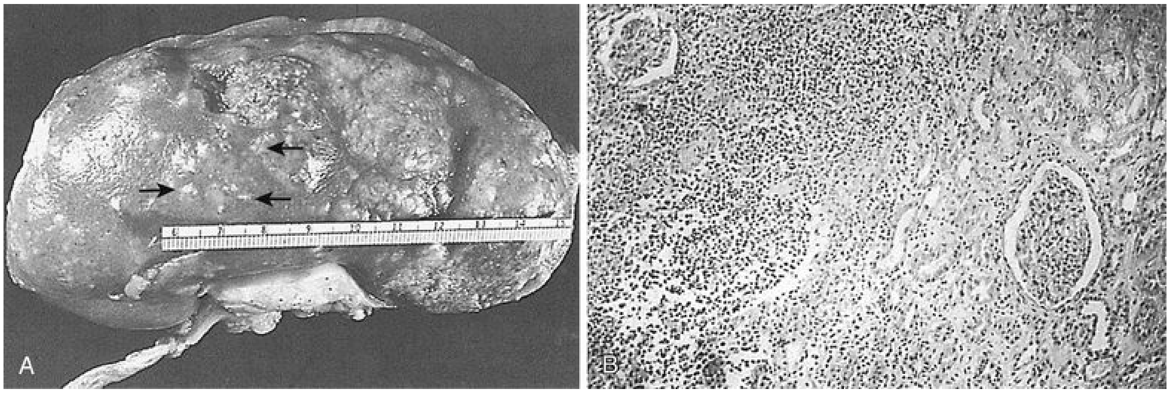

FIG. 55.18 Acute focal suppurative bacterial nephritis. (A) Surface of kidney. *Arrows* indicate focal areas of suppuration. (B) Renal cortex showing focal suppuration destruction of glomeruli and tubules. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology*, Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

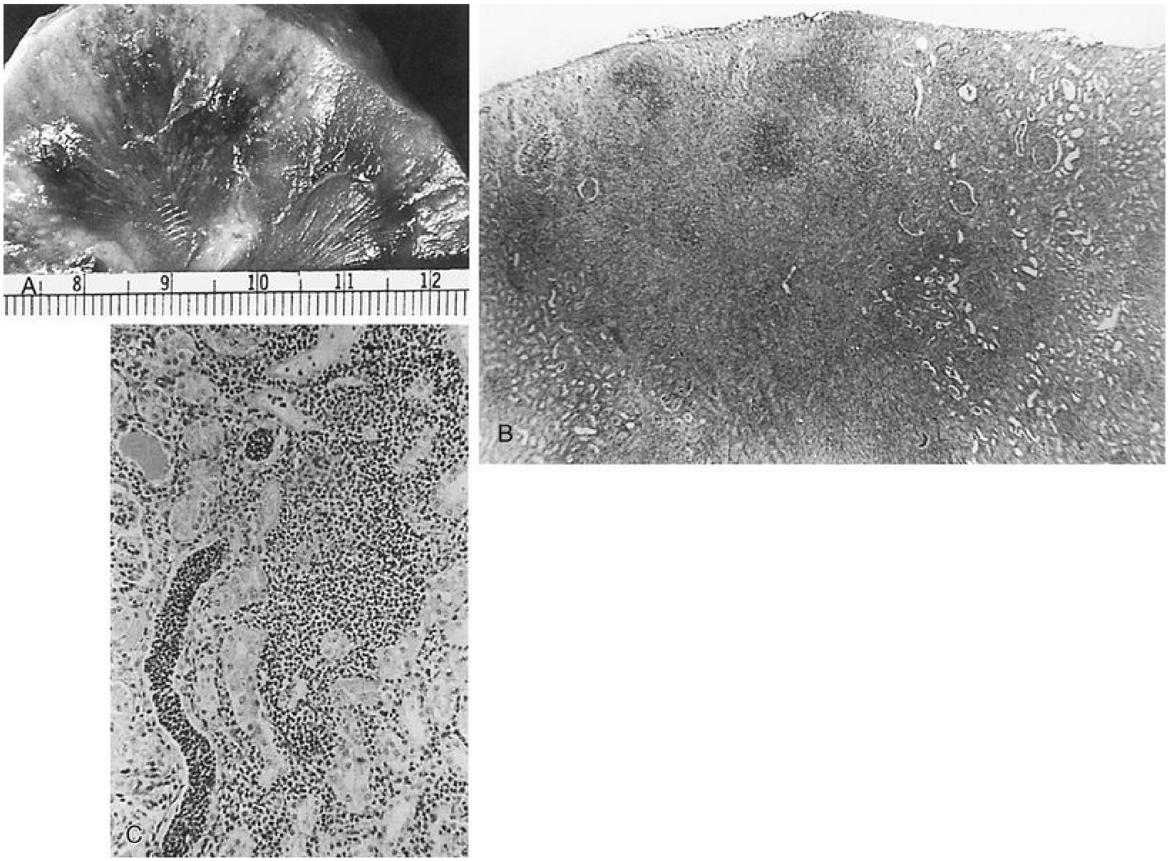

FIG. 55.19 Acute ascending pyelonephritis. (A) Cortical structures, tubules, and collecting ducts diffusely infiltrated with inflammatory cells. (B) Section of the renal cortex showing wedge-shaped destruction of renocortical structures as a result of ascending infiltration with inflammatory cells. (C) Thickened and inflamed tissue surrounding the collecting ducts in the medulla. A polymorphonuclear cast of segmented neutrophils is clearly visible. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

The changes that appear to be most specific for **chronic pyelonephritis** are evident on careful gross examination of the kidney and consist of a cortical scar associated with retraction of the corresponding renal papilla (Freedman, 1979; Heptinstall, 1974; Hodson, 1965; Hodson and Wilson, 1965). The kidney shows evidence of patchy involvement with numerous chronic inflammatory foci mainly confined to the cortex but also involving the medulla (Fig. 55.20).

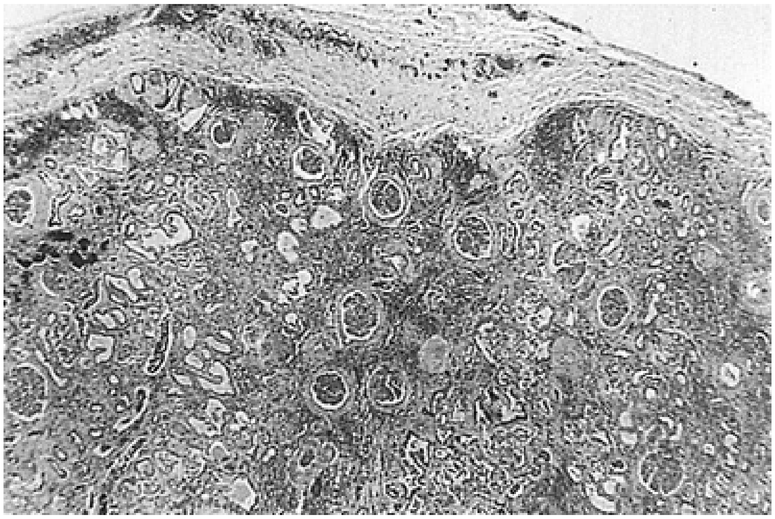

FIG. 55.20 Chronic pyelonephritis. The renal cortex shows thickened fibrous capsule and focal retracted scar on surface of kidney. Focal destruction of tubules in center of picture is accompanied by periglomerular fibrosis and scarring. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

The scars may be separated by intervening zones of normal parenchyma, causing a grossly irregular renal outline. The microscopic appearance, as with most chronic interstitial disease, includes the presence of lymphocytes and plasma cells. Although glomeruli within scars may be surrounded by a cuff of fibrosis or be partially or completely hyalinized, glomeruli outside these severely scarred zones are relatively normal. Vascular involvement is variable, but in patients with hypertension, nephrosclerosis may be found. Papillary abnormalities include deformity, sclerosis, and sometimes necrosis. Studies in animals have clearly indicated the critical role of the papilla in the initiation of pyelonephritis (Freedman and Beeson, 1958). However, these changes are not necessarily specific for bacterial infection and may occur in the absence of infection as a result of other disorders such as analgesic abuse, diabetes, and sickle cell disease.

Acute Pyelonephritis

Although pyelonephritis is defined as inflammation of the kidney and renal pelvis, the diagnosis is clinical. True infection of the "upper urinary tract" can be proved by catheterization tests (ureteral catheterization or bladder washout) as described in this chapter, but these are impractical and unnecessary in most patients with acute pyelonephritis. None of the noninvasive tests that have been developed to determine infection in the kidney or bladder are totally reliable.

Clinical Presentation.

The clinical spectrum ranges from gram-negative sepsis to cystitis with mild flank pain (Stamm and Hooton, 1993)**. The classic presentation is an abrupt onset of chills, fever (100.3°F or greater), and unilateral or bilateral flank or costovertebral angle pain and/or tenderness. These so-called upper tract signs are sometimes accompanied by dysuria, increased urinary frequency, and urgency, but in many cases lower urinary symptoms are not present.**

Although some authors regard loin pain and fever in combination with significant bacteriuria as diagnostic of acute pyelonephritis, it is clear from localization studies using ureteral catheterization (Stamey and Pfau, 1963) or the bladder washout technique (Fairley et al., 1967) that **clinical symptoms correlate poorly with the site of infection** (Eykyn et al., 1972; Fairley, 1972; Smeets and Gower, 1973; Stamey et al., 1965).

On physical examination, there often is tenderness to deep palpation in the costovertebral angle. Variations of this clinical presentation have been recognized. Acute pyelonephritis may also simulate GI tract abnormalities with abdominal pain, nausea, vomiting, and diarrhea. Asymptomatic progression of acute pyelonephritis to chronic pyelonephritis, particularly in compromised hosts, may occur in the absence of overt symptoms. Acute renal failure may be present in the rare case (Olsson et al., 1980; Richet and Mayaud, 1978).

Laboratory Diagnosis.

The patient may have leukocytosis with a predominance of neutrophils. **Urinalysis usually reveals numerous WBCs, often in clumps, and bacterial rods or chains of cocci. The presence of large amounts of granular or leukocyte casts in the urinary sediment is suggestive of acute pyelonephritis.** A specific type of urinary cast characterized by the presence of bacteria in its matrix has been demonstrated in the urine of patients who have had acute pyelonephritis (Fig. 55.21; Lindner et al., 1980). Blood tests may show leukocytosis with a predominance of neutrophils, increased erythrocyte sedimentation rate, elevated C-reactive protein levels, and elevated creatinine levels if renal failure is present. In addition, creatinine clearance may be decreased. Blood cultures may be positive.

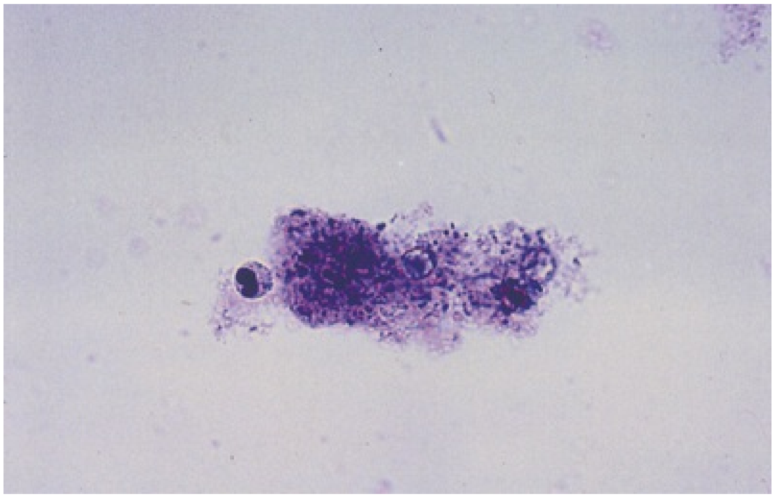

FIG. 55.21 Brightfield micrograph of a mixed bacterial leukocyte cast from patient with acute pyelonephritis. Only the bacteria and the nucleus of a leukocyte stain strongly. Many bacteria are clearly demonstrated by through-focusing (toluidine blue O stain, magnification ×640). (Modified from Lindner LE, Jones RN, Haber MH: A specific urinary cast in acute pyelonephritis. *Am J Clin Pathol* 73:809–811, 1980.)

Bacteriology.

Urine cultures are positive, but about 20% of patients have urine cultures with fewer than 10^5 CFU/mL and therefore negative results on Gram staining of the urine (Rubin et al., 1992).

***E. coli*, which constitutes a unique subgroup that possesses special virulence factors, accounts for 80% of cases.** If VUR is absent, a patient bearing the P blood group phenotype may have special susceptibility to recurrent pyelonephritis caused by *E. coli* that have P pili and bind to the P blood group antigen receptors (Lomberg et al., 1983). Bacterial K antigens and endotoxins also may contribute to pathogenicity (Kaijser et al., 1977). Many cases of community-acquired pyelonephritis are caused by a limited number of multiantimicrobial-resistant clonal groups (Manges et al., 2004).

More resistant species, such as *Proteus, Klebsiella, Pseudomonas, Serratia, Enterobacter,* or *Citrobacter,* should be suspected in patients who have recurrent UTIs, are hospitalized, or have indwelling catheters, as well as in those who required recent urinary tract instrumentation. Except for *E. faecalis, S. epidermidis,* and *S. aureus,* gram-positive bacteria rarely cause pyelonephritis.

Blood cultures are positive in about 25% of cases of uncomplicated pyelonephritis in women, and the majority replicate the urine culture and

do not influence decisions regarding therapy. Therefore blood cultures should not be routinely obtained for the evaluation of uncomplicated pyelonephritis in women. **However, they should be performed in men and women with systemic toxicity or in those requiring hospitalization or with risk factors such as pregnancy** (Velasco et al., 2003).

Renal Ultrasonography, Computed Tomography, and Magnetic Resonance Imaging.

Ultrasound may show focal parenchymal swelling and regions of increased or decreased echogenicity (Fig. 55.22). CT and MRI also may show focal swelling and diminished and inhomogeneous parenchymal contrast enhancement (Fig. 55.23). Without contrast, CT may show diminished density of affected areas and MRI may show regions of restricted diffusion. Acute pyelonephritis may cause chronic renal scarring; however, radiographic changes usually resolve; therefore future renal imaging will show a normal-appearing kidney.

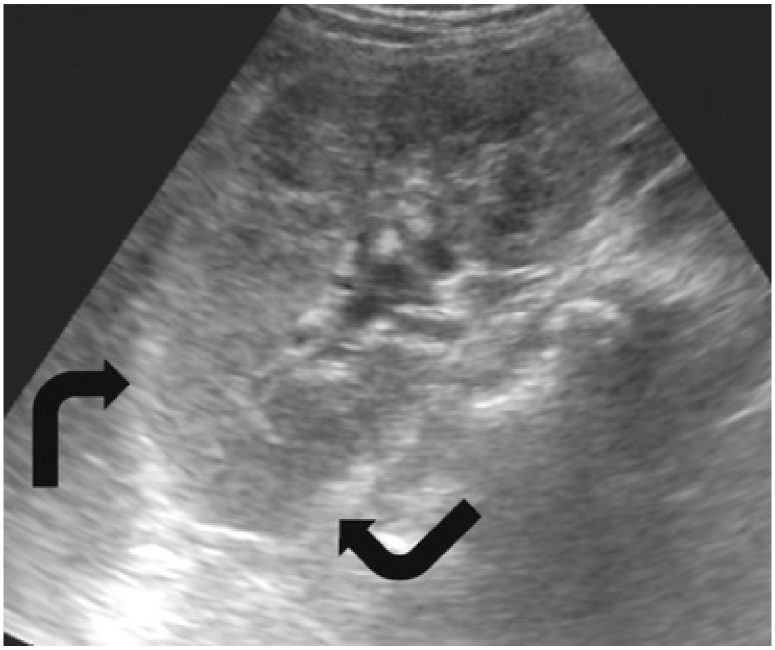

FIG. 55.22 Ultrasound of acute pyelonephritis. *Arrows* show abnormally echogenic and swollen upper pole.

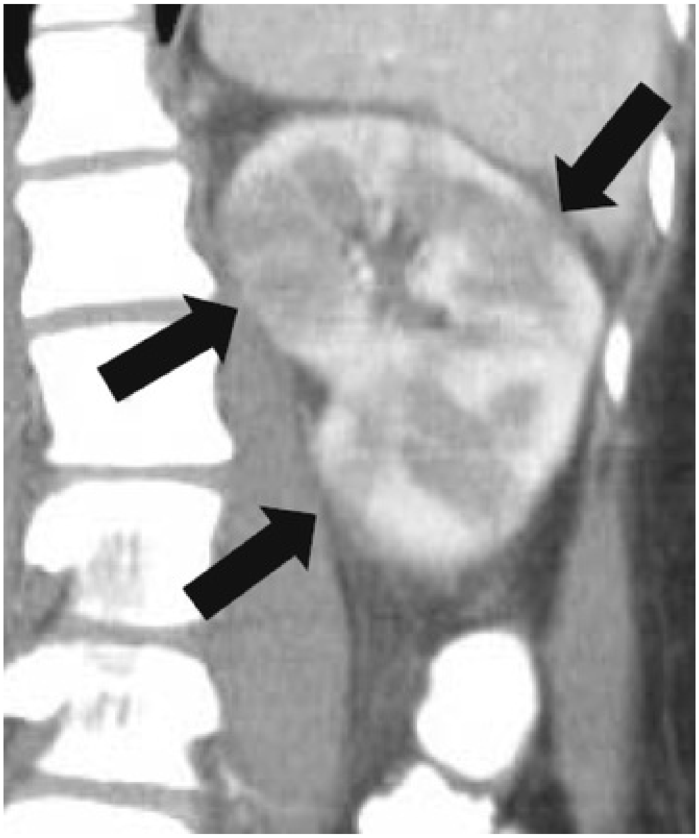

FIG. 55.23 Computed tomography of focal pyelonephritis. *Arrows* show patchy regions of diminished heterogeneous enhancement and swelling.

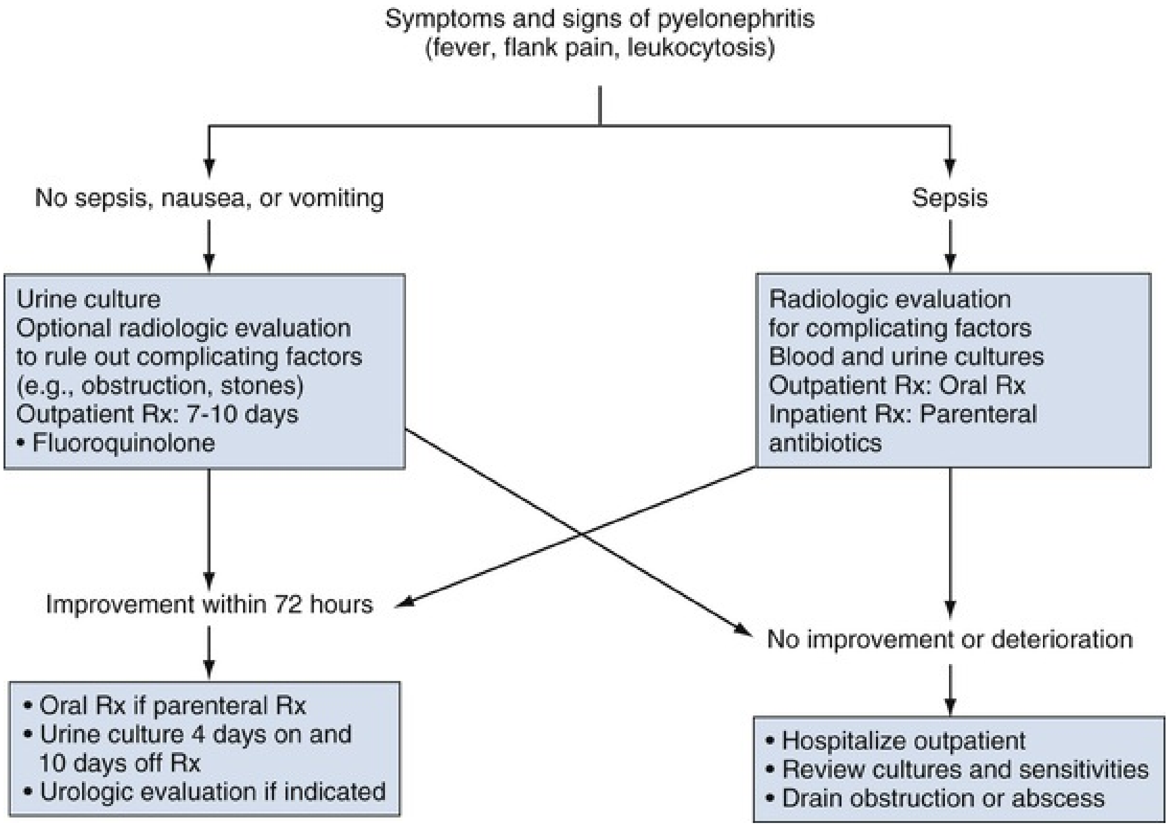
Differential Diagnosis.

Acute appendicitis, diverticulitis, and pancreatitis can cause a similar degree of pain, but the location of the pain often is different. Results of the urine examination are usually normal. Herpes zoster can cause superficial pain in the region of the kidney but is not associated with symptoms of UTI; the diagnosis will be apparent when shingles appear.

Management

Initial Management.

Infection in patients with acute pyelonephritis can be subdivided into (1) uncomplicated infection that does not warrant hospitalization, (2) uncomplicated infection in patients with normal urinary tracts who are ill enough to warrant hospitalization for parenteral therapy, and (3) complicated infection associated with hospitalization, catheterization, urologic surgery, or urinary tract abnormalities (Fig. 55.24).



Symptoms and signs of pyelonephritis
(fever, flank pain, leukocytosis)
No sepsis, nausea, or vomiting
Sepsis
Urine culture
Optional radiologic evaluation
to rule out complicating factors
(e.g., obstruction, stones)
Outpatient Rx: 7-10 days
• Fluoroquinolone
Radiologic evaluation
for complicating factors
Blood and urine cultures
Outpatient Rx: Oral Rx
Inpatient Rx: Parenteral
antibiotics
Improvement within 72 hours
No improvement or deterioration
• Oral Rx if parenteral Rx
• Urine culture 4 days on and
10 days off Rx
• Urologic evaluation if indicated
• Hospitalize outpatient
• Review cultures and sensitivities
• Drain obstruction or abscess

FIG. 55.24 Management of acute pyelonephritis.

It is critical to determine whether the patient has an uncomplicated or complicated UTI because significant abnormalities have been found in 16% of patients with acute pyelonephritis (Shen and Brown, 2004). In patients with presumed uncomplicated pyelonephritis who will be managed as outpatients, initial radiologic evaluation can usually be deferred. **However, if there is any reason to suspect a problem or if the patient will not have reasonable access to imaging if there should be no change in condition, we prefer renal ultrasonography to rule out stones or obstruction.** In patients with known or suspected complicated pyelonephritis, CT provides excellent assessment of the status of the urinary tract and the severity and extent of the infection.

Oral ciprofloxacin (500 mg twice daily) for 7 days is an appropriate first-line therapy in patients not requiring hospitalization where the prevalence of uropathogen resistance to quinolones in the community does not exceed 10%, as per the IDSA guidelines on management of acute pyelonephritis (Gupta et al., 2011). If an initial one-time parenteral dose of antibiosis is chosen, a long-acting agent such as 1 g of ceftriaxone or a consolidated 24-hour dose of an aminoglycoside can be used as an alternative to an intravenous fluoroquinolone (Gupta et al., 2011). Once-daily oral fluoroquinolones, such as ciprofloxacin 1000 mg extended release for 7 days or levofloxacin 750 mg for 5 days, are also reasonable alternatives in non-hospitalized patients in whom resistance patterns in the community are low (Gupta et al., 2011). Oral TMP-SMX (160/800 mg [1 double-strength tablet] twice daily for 14 days) is an appropriate agent if the organism is known to be sensitive; if the susceptibility is unknown, an initial intravenous dose of a long-acting parenteral antibiotic, such as 1 g ceftriaxone or a consolidated 24-hour dose of an aminoglycoside is recommended (Gupta et al., 2011; Talan et al., 2000) (Table 55.11). As mentioned in previous sections, with the emerging resistance and potential for collateral damage associated with quinolones, future guidelines will likely need to address the role of cephalosporins for outpatient treatment of pyelonephritis.

TABLE 55.11

Treatment Regimens for Acute Complicated and Uncomplicated Pyelonephritis in Women

CIRCUMSTANCES	ROUTE	DRUG	DOSAGE[e]	FREQUENCY PER DOSE	DURAT (DAYS)
Outpatient—moderately ill, no nausea or vomiting	Oral[a]	TMP-SMX DS[b]	160–800 mg	q12h	14
		Ciprofloxacin[c]	500 mg	q12h	7
		Ciprofloxacin[c] (extended release)	1000 mg	q24h	7
		Levofloxacin[c]	750 mg	q24h	5
Inpatient—severely ill, possible sepsis	Parenteral[d]	Ampicillin and gentamicin	1–2 g	q6h	10–14
			1–1.5 mg/kg	q8h	
		Levofloxacin[c]	500–750 mg	q24h	10–14
		Ceftriaxone	1 g	q24h	10–14
		Carbapenem	(dosage varies)		10–14
Pregnant	Parenteral[d]	Ampicillin	1–2 g	q6h	10–14

		and gentamicin			
			1–1.5 mg/kg	q8h	
		Aztreonam	1 g	q8h	10–14
	Oral	Cephalexin	500 mg	q6h	

[a] May be given with an initial 1-time intravenous dose of a long-acting parenteral antimicrobial such as 1 g of ceftriaxone or a consolidated 24-hour dose of an aminoglycoside. See IDSA recommendations.

[b] Appropriate choice if uropathogen is known to be susceptible. If susceptibility is unknown, an initial dose of long-acting parenteral antimicrobial such as 1 g of ceftriaxone or a consolidated 24-hour dose of an aminoglycoside is recommended.

[c] May be used in areas where the prevalence of resistance of community uropathogens to fluoroquinolones is not known to exceed 10%.

[d] For parenteral agents, take until afebrile then transition to oral agents according to sensitivities.

[e] All dosages should be adjusted for renal function.

DS, Double strength; *TMP-SMX,* trimethoprim-sulfamethoxazole.

If a patient has an uncomplicated infection but is sufficiently ill to require hospitalization (high fever, high WBC count, vomiting, dehydration, evidence of sepsis), has complicated pyelonephritis, or fails to improve during the initial outpatient treatment period, a parenteral antibiotic is recommended. In women with pyelonephritis requiring hospital admission, recent IDSA guidelines recommend an intravenous regimen such as a fluoroquinolone, an aminoglycoside with or without ampicillin, an extended-spectrum cephalosporin with or without an aminoglycoside, or a carbapenem (Gupta et al., 2011; Warren et al., 1999). If gram-positive cocci are causative, ampicillin/sulbactam with or without an aminoglycoside is recommended.

Hospitalization, IV fluids, and antipyretics are required.

Overall kidney function is not affected in the presence of unilateral obstruction. **However, a solitary obstructed kidney causes acute renal failure; antimicrobial agents are dosed based on the GFR. Any substantial obstruction must be relieved expediently by the safest and simplest means, such as ureteral stent or percutaneous nephrostomy tube placement.**

A Gram stain of the urine sediment is helpful to guide the selection of the initial empirical antimicrobial therapy. In all cases, antimicrobial therapy should be active against potential uropathogens and achieve antimicrobial levels in renal tissue and urine.

Subsequent Management.

Even though the urine usually becomes sterile within a few hours of starting antimicrobial therapy, patients with acute uncomplicated pyelonephritis may continue to have fever, chills, and flank pain for several more days after initiation of successful antimicrobial therapy (Behr et al., 1996). They should be observed.

Alterations in antimicrobial therapy may be made depending on the patient's clinical response and the results of the culture and susceptibility tests. Susceptibility tests should also be used to replace potentially toxic drugs, such as aminoglycosides, with less toxic drugs, such as aztreonam and cephalosporins.

Patients with complicated pyelonephritis and positive blood cultures should be treated with parenteral therapy until clinically stable. If blood cultures are negative, 2- to 3-day parenteral therapy is sufficient. After parenteral therapy, an appropriate oral antimicrobial drug (fluoroquinolone, TMP, TMP-SMX, or amoxicillin or amoxicillin/clavulanic acid for gram-positive organisms) should be continued in full dosage for an additional 10 to 14 days.

Unfavorable Response to Therapy.

When the response to therapy is slow or the urine continues to show infection, an immediate reevaluation is mandatory. Urine and blood cultures must be repeated and appropriate alterations in antimicrobial therapy made on the basis of susceptibility testing. CT is indicated to attempt to identify unsuspected obstructive uropathy, abscess formation, urolithiasis, or underlying anatomic abnormalities that may have predisposed the patient to infection, prevented a rapid therapeutic response, or caused complications of the infectious process, such as renal or perinephric abscess. **In patients with fever lasting longer than 72 hours, CT is most helpful for ruling out obstruction and identifying renal and perirenal infections** (Soulen et al., 1989). Radionuclide imaging may be useful to demonstrate functional changes associated with acute pyelonephritis (decrease in renal blood flow, delay in peak function, and delay in excretion of the radionuclide) (Fischman and Roberts, 1982) and cortical defects associated with VUR.

Follow-Up.

Depending on the clinical presentation and response and initial urologic evaluation, some patients may require additional evaluation (e.g., VCUG, cystoscopy, bacterial localization studies) and correction of an underlying abnormality of the urinary tract. Raz et al. (2003) evaluated the long-term impact of acute pyelonephritis in women. Scanning with ^{99m}Tc-dimercaptosuccinic acid (^{99m}Tc-DMSA) 10 to 20 years after acute pyelonephritis revealed scars in approximately 50% of the patients, but changes in renal function were minimal and not associated with renal scarring.

Acute Focal or Multifocal Bacterial Nephritis

Acute focal or multifocal bacterial nephritis is an uncommon, severe form of acute renal infection in which a heavy leukocyte infiltrate is confined to a single renal lobe (focal) or multiple lobes (multifocal).

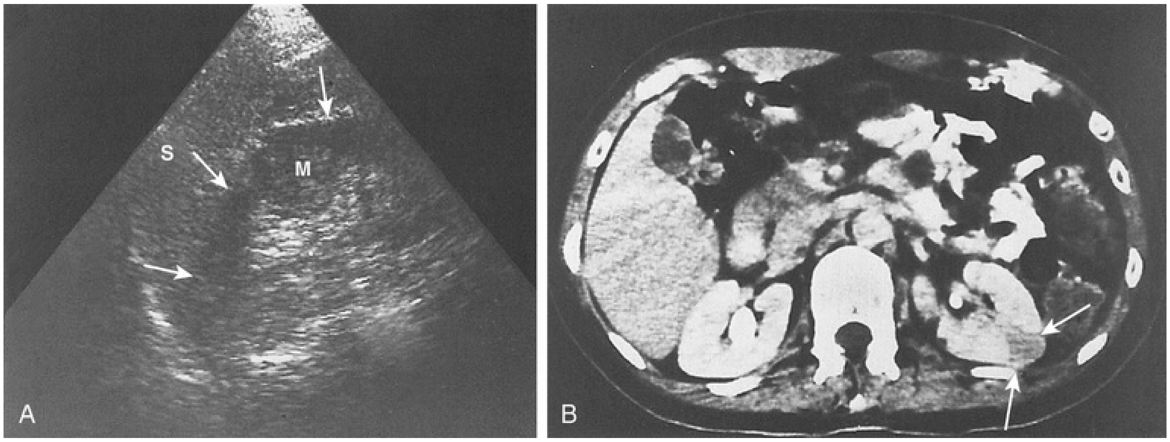
Clinical Presentation.

The clinical presentation of patients with acute bacterial nephritis is similar to that of patients with acute pyelonephritis but usually is more severe. About half of the patients are diabetic, and sepsis is common. Generally, leukocytosis and UTI resulting from gram-negative organisms are found; more than 50% of the patients are bacteremic (Wicks and Thornbury, 1979). There is growing evidence that acute focal bacterial nephritis (AFBN) represents a midpoint on the spectrum between pyelonephritis and renal abscess.

Radiologic Findings.

The diagnosis must be made by radiologic examination. The mass has slightly less nephrographic density than the surrounding normal renal parenchyma.

Ultrasonography and CT establish the diagnosis. On ultrasonography, the lesion is typically poorly marginated and relatively sonolucent with occasional low-amplitude echoes that disrupt the cortical medullary junction (Corriere and Sandler, 1982; eFig. 55.25A). **Enhancement with a contrast agent is necessary with CT studies because the lesion is difficult to visualize on the unenhanced study** (eFig. 55.25B). **Wedge-shaped areas of decreased enhancement are seen.** No definite wall is evident, and frank liquefaction is absent. Conversely, abscesses tend to have liquid centers, are usually round, and are present before and after contrast medium enhancement. More chronic abscesses may also show a ring-shaped area of increased enhancement surrounding the lesion (Corriere and Sandler, 1982). Gallium scanning reveals uptake that is in the region of and larger than the previously demonstrated mass (Rosenfield et al., 1979). In patients with multifocal disease, the findings are similar but multiple lobes are involved.



EFIG. 55.25 Acute focal bacterial nephritis. (A) Ultrasound image; longitudinal view of the left kidney demonstrates spleen *(S)* and left kidney *(arrows).* Note irregular midpole mass *(M)* of slightly higher echo texture than surrounding normal renal parenchyma. (B) Contrast medium–enhanced computed tomography scan demonstrates a wedge-shaped area of low density *(arrows)* in the middle portion of the left kidney. The findings resolved after antimicrobial therapy. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

Management.

Acute bacterial nephritis probably represents a relatively early phase of frank abscess formation. In a series of cases reported by Lee et al. (1980), a patient with acute focal bacterial nephritis progressed to abscess formation. McCoy et al. (1985) reported radiographically proven progression from acute nephritis to an abscess despite appropriate medical management. Shimizu et al. (2005) presented a case of a 16-year-old female with CT imaging consistent with AFBN and no evidence of drainable fluid collection, which progressed by hospital day 13 to a hypodense large abscess in the area previously seen to be nephritis while being treated. **Treatment includes hydration and IV antimicrobial agents for at least 7 days, followed by 7 days of oral antimicrobial therapy.** Patients with bacterial nephritis typically respond to medical therapy, and follow-up studies will show resolution of the wedge-shaped zones of diminished attenuation. **Failure to respond to antimicrobial therapy is an indication for appropriate studies to rule out obstructive uropathy, renal or perirenal**

abscess, renal carcinoma, or acute renal vein thrombosis. Long-term follow-up studies performed in a few patients with multifocal disease have demonstrated a decrease in renal size and focal calyceal deformities suggestive of papillary necrosis (Davidson and Talner, 1978).

Emphysematous Pyelonephritis

Emphysematous pyelonephritis is a urologic emergency characterized by an acute necrotizing parenchymal and perirenal infection caused by gas-forming uropathogens. The pathogenesis is poorly understood. **Because the condition usually occurs in patients with diabetes, it has been postulated that the high tissue glucose levels provide the substrate for microorganisms such as *E. coli,* which are able to produce carbon dioxide by the fermentation of sugar** (Schainuck et al., 1968). Although glucose fermentation may be a factor, the explanation does not account for the rarity of emphysematous pyelonephritis despite the high frequency of gram-negative UTI in patients with diabetes, nor does it explain the rare occurrence of the condition in nondiabetic patients.

In addition to diabetes, many patients have urinary tract obstruction associated with urinary calculi or papillary necrosis and significant renal functional impairment. The overall mortality rate has been reported to be between 19% (Huang and Tseng, 2000) and 43% (Freiha et al., 1979).

Clinical Presentation.

Nearly all of the documented cases of emphysematous pyelonephritis have occurred in adults (Hawes et al., 1983). Juvenile patients with diabetes do not appear to be at risk. Women are affected more often than men.

The usual clinical presentation is severe, acute pyelonephritis, although in some instances a chronic infection precedes the acute attack. **Almost all patients display the classic triad of fever, vomiting, and flank pain** (Schainuck et al., 1968). Emphysematous pyelonephritis affects predominantly female patients with diabetes and can occur in insulin-dependent and non–insulin-dependent patients in the absence of ureteral obstruction. Patients without diabetes can also develop this form of pyelonephritis but often have ureteric obstruction and do not seem to develop extensive disease (Pontin and Barnes, 2009). Pneumaturia is absent unless the infection involves the collecting system. Results of urine cultures are invariably positive. *E. coli* is most commonly identified. *Klebsiella* and *Proteus* spp. are less common.

Radiologic Findings.

The diagnosis is established radiographically. Tissue gas that is distributed in the parenchyma may appear on abdominal radiographs as mottled gas shadows over the involved kidney (Fig. 55.26). This finding is often mistaken for bowel gas. A crescentic collection of gas over the upper pole of the kidney is more distinctive. As the infection progresses, gas extends to the perinephric space and retroperitoneum. This distribution of gas should not be confused with cases of emphysematous pyelitis in which air is in the collecting system of the kidney. Emphysematous pyelitis is secondary to a gas-forming bacterial UTI, often occurs in patients without diabetes, is less serious, and usually responds to antimicrobial therapy.

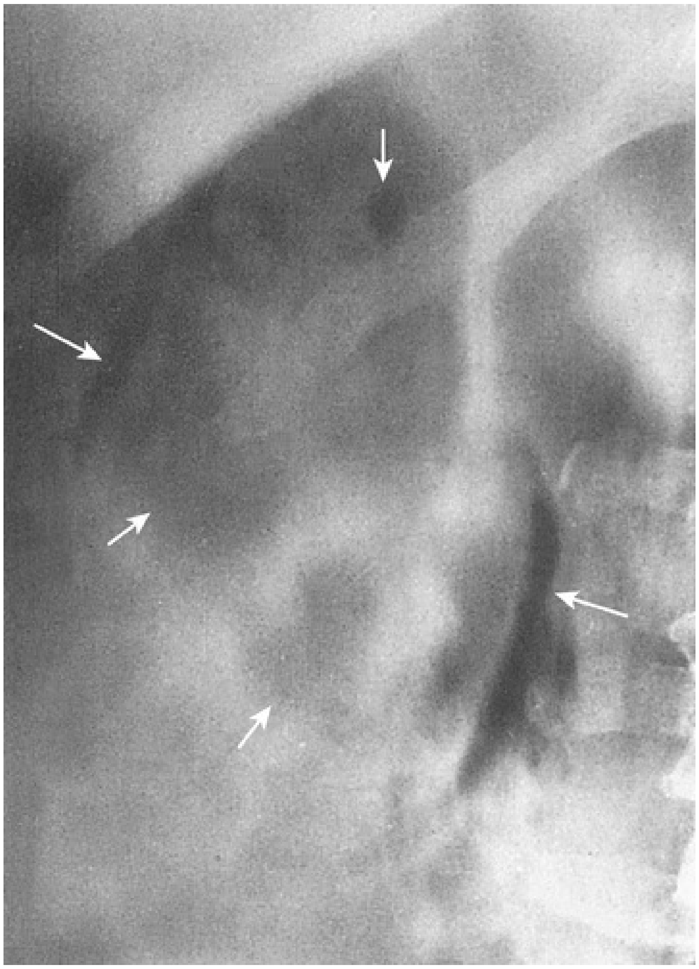


FIG. 55.26 Emphysematous pyelonephritis; plain film. Extensive perinephric *(long arrows)* and intraparenchymal *(short arrows)* gas secondary to acute bacterial pyelonephritis. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors:

Adult and pediatric urology, Philadelphia, 2002, Lippincott William & Wilkins, pp 211–272.)

Ultrasonography usually demonstrates strong focal echoes suggesting the presence of intraparenchymal gas (Brenbridge et al., 1979; Conrad et al., 1979). **CT is the imaging procedure of choice in defining the extent of the emphysematous process and guiding management** (Fig. 55.27). **An absence of fluid in CT images or the presence of streaky or mottled gas with or without bubbly and loculated gas appears to be associated with rapid destruction of renal parenchyma and a 50% to 60% mortality rate** (Best et al., 1999; Wan et al., 1996). The presence of renal or perirenal fluid, the presence of bubbly or loculated gas or gas in the collecting system, and the absence of streaky or mottled gas patterns are associated with a less than 20% mortality rate.

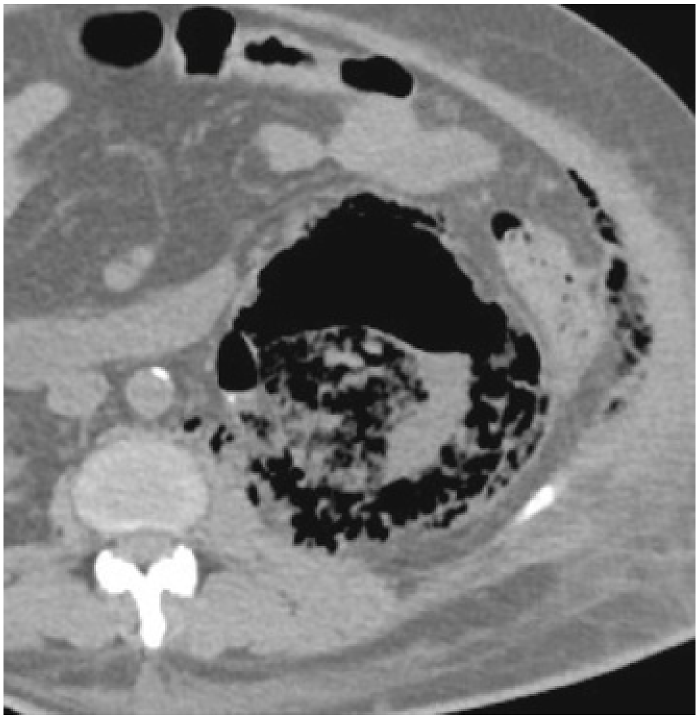

FIG. 55.27 Computed tomography of emphysematous pyelonephritis. There is air within and surrounding the left kidney.

In line with these observations, in 2000, Huang and Tseng developed a radiologic classification system based on the extent of gas involvement in the renal tissue on CT scan that has been used to help guide management; the system uses a four-category system that grades progressively more gas involvement with the renal and adjacent renal tissue with ascension through the classes (Huang, 2000).

Obstruction is demonstrated in approximately 25% of the cases. A nuclear renal scan should be performed to assess the degree of renal function impairment in the involved kidney and the status of the contralateral kidney.

Management.

Emphysematous pyelonephritis is a urologic emergency. Most patients are septic, and fluid resuscitation, glucose and electrolyte management, and broad-spectrum antimicrobial therapy are essential. Ureteral obstruction, if present, is alleviated by a percutaneous nephrostomy tube or a stent (Pontin and Barnes, 2009). Hypoalbuminemia, shock at initial presentation, bacteremia, indications for hemodialysis, thrombocytopenia, altered mental status, and polymicrobial infection are among various prognostic risk factors that have been associated with increased mortality in different outcomes studies involving emphysematous pyelonephritis patients (Huang and Tseng, 2000; Lu et al., 2014). Treatment has evolved over the years from nephrectomy to more conservative management with percutaneous catheter drainage or the use of a double-J ureteral stent depending on the severity of presentation. Until the late 1980s, management involved emergency nephrectomy with or without open surgical drainage and antibiosis, although this management was still associated with a mortality rate of 40% to 50% (Ahlering et al., 1985; Michaeli et al., 1984). Since this time, the overall mortality rate has decreased with advancements in medicine, and **definitive management is by percutaneous drainage, except in cases of extensive diffuse gas with renal destruction; in this latter scenario, nephrectomy is advised** (Huang and Tseng, 2000; Pontin and Barnes, 2009). Early diagnosis and treatment of patients with diabetes and urinary infection is important to potentially avoid progression of this disease process and in turn nephrectomy (Pontin and Barnes, 2009).

Renal Abscess

Renal abscess or carbuncle is a collection of purulent material confined to the renal parenchyma. Before the antimicrobial era, 80% of renal abscesses were attributed to hematogenous seeding by staphylococci (Campbell, 1930). In addition, historically, patients with abscesses were young men with no prior renal disease. Although experimental and clinical data document the facility for abscess formation in normal kidneys after hematogenous inoculation with staphylococci, widespread use of antimicrobial agents since about 1950 appears to have diminished the propensity for gram-positive abscess formation (Cotran, 1969; DeNavasquez, 1950). The current index patient typically has a history of renal disease or obstruction, no gender predominance, and no laterality, and the infection is typically with a gram-negative organism.

Since about 1970, gram-negative organisms have been implicated in the majority of adults with renal abscesses. The most common organisms include *E. coli, Klebsiella, Proteus,* and *Pseudomonas* spp. (Fowler and Perkins, 1994; Shu et al., 2004). Hematogenous renal seeding by gram-negative organisms may occur, but this is not likely to be the primary pathway for gram-negative abscess formation. Clinically, there is no evidence that gram-negative septicemia antedates most lesions. Further, gram-negative hematogenous pyelonephritis is almost impossible to produce in animals unless the kidney is traumatized or completely obstructed (Cotran, 1969; Timmons and Perlmutter, 1976). Like the normal kidney, the partially obstructed kidney rejects blood-borne gram-negative inocula. Thus ascending infection associated with tubular obstruction from prior infections or calculi appears to be the primary pathway for the establishment of gram-negative abscesses. Two-thirds of gram-negative abscesses in adults are associated with renal calculi or damaged kidneys (Salvatierra et al., 1967; Siegel et al., 1996). Although the association of pyelonephritis with VUR is well established, the association of renal abscess with VUR has been infrequently noted (Segura and Kelalis, 1973). Case reports in the pediatric literature exist, but literature within the adult population is sparse. More recent observations, however, indicate that reflux is frequently associated with renal abscesses and persists long after sterilization of the urinary tract (Anderson and McAninch, 1980; Timmons and Perlmutter, 1976). Renal abscesses are also associated with IV drug abuse.

Clinical Presentation.

The patient may present with fever, chills, abdominal or flank pain, and occasionally weight loss and malaise. Symptoms of cystitis may occur. Occasionally, these symptoms may be vague and delay diagnosis until surgical exploration or, in more severe cases, autopsy (Anderson and McAninch, 1980). **A thorough history may reveal a gram-positive source of infection 1 to 8 weeks before the onset of urinary tract symptoms or symptoms consistent with UTI or pyelonephritis in the weeks prior** (Hung et al., 2007)**. The infection may have occurred in any area of the body.** Multiple skin carbuncles and IV drug abuse introduce gram-positive organisms into the bloodstream. Other common sites are the mouth, lungs, and bladder (Lyons et al., 1972). Complicated UTIs associated with stasis, calculi, pregnancy, neurogenic bladder, and diabetes mellitus also appear to predispose the patient to abscess formation (Anderson and McAninch, 1980).

Shu et al. (2004) published their experience with 26 cases of renal/perirenal abscesses with anatomically normal GU tracts, and no stones or prior urologic manipulation. In 24 of the 26 cases, the patients had at least 1 predisposing factor (diabetes mellitus, HIV, steroid use, IV drug abuse, liver disease, UTI, pregnancy). Diabetes mellitus is noted to be a very significant risk factor for development of renal abscesses, as is increased length of hospitalization (Ko et al., 2011, 2013).

Laboratory Diagnosis.

The patient typically has marked leukocytosis. In a series by Siegel et al. (1996) of 52 patients, blood cultures were positive 28% of the time, whereas Yen et al. (1999) published a series of 78 patients, 25 of which (32%) had positive blood cultures. In comparison of positive cultures in all three types of fluids (abscess, blood, urine) only 1 patient of the 78 had identical isolates in all three. Urine and abscess culture had a 15% identical culture rate, whereas blood and abscess had a 13% identical culture rate (Yen et al., 1999). Pyuria and bacteriuria may not be evident unless the abscess communicates with the collecting system. **Because gram-positive organisms are most commonly blood-borne, urine cultures in these cases typically show no growth or a microorganism different from that isolated from the abscess.** Another study showed not only a bacteremia rate of 26% but also that positive urine cultures were only present in roughly 30% of patients (Shu et al., 2004).

Ultrasonography and CT distinguish abscess from other inflammatory renal diseases. **Ultrasonography is the quickest and least expensive method to demonstrate a renal abscess. An echo-free or low-echodensity space-occupying lesion with increased transmission is found on the ultrasound image** (Fig. 55.28). The margins of an abscess are indistinguishable in the acute phase, but the structure contains a few echoes and the surrounding renal parenchyma is edematous (Fiegler, 1983). Subsequently, the appearance tends to be that of a well-defined mass. The internal appearance, however, may vary from a virtually solid lucent mass to one with large numbers of low-level internal echoes (Schneider et al., 1976). The number of echoes depends on the amount of cellular debris within the abscess. The presence of air results in a strong echo with a shadow. Differentiation between an abscess and a tumor is impossible in many cases. Arteriography is used infrequently to demonstrate abscesses. The center of the mass tends to be hypervascular or avascular, with increased vascularity at the cortical margins and lack of vascular displacement and neovascularity.

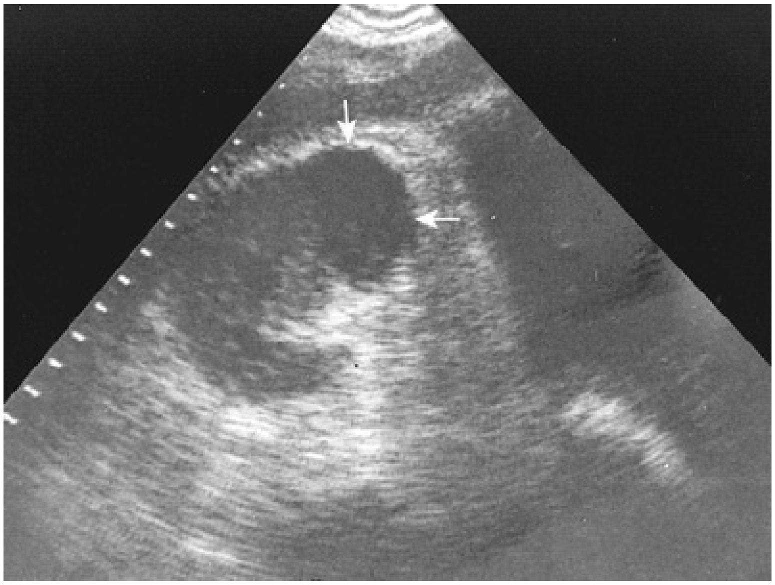

FIG. 55.28 Acute renal abscess. Transverse ultrasound image of the right kidney demonstrates a poorly marginated rounded focal hypoechoic mass *(arrows)* in the anterior portion of the kidney.

CT appears to be the diagnostic procedure of choice for renal abscesses because it provides excellent delineation of the tissue. On CT, abscesses are characteristically well defined before and after contrast agent enhancement. The findings depend in part on the age and severity of the abscess (Baumgarten and Baumgartner, 1997). Initially, CT shows renal enlargement and focal, rounded areas of decreased attenuation (Fig. 55.29). After several days of the onset of the infection, a thick fibrotic wall begins to form around the abscess. An echo-free or slightly echogenic mass caused by the presence of necrotic debris is seen. CT of a chronic abscess shows obliteration of adjacent tissue planes, thickening of the Gerota fascia, a round or oval parenchymal mass of low attenuation, and a surrounding inflammatory wall of slightly higher attenuation that forms a ring when the scan is enhanced with contrast material (Fig. 55.30). The ring sign is caused by the increased vascularity of the abscess wall (Callen, 1979; Gerzof and Gale, 1982).

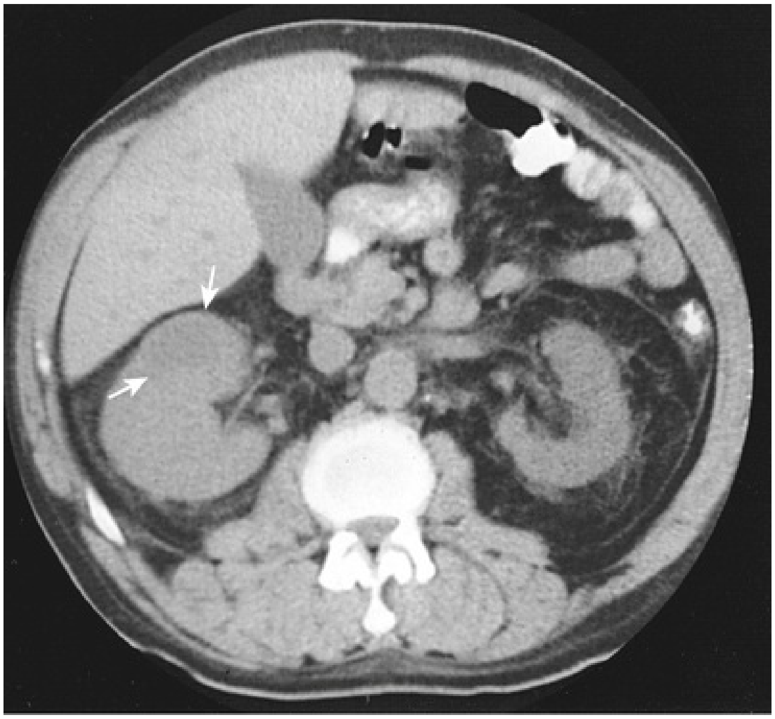

FIG. 55.29 Acute renal abscess. Nonenhanced computed tomography scan through the mid pole of the right kidney demonstrates right renal enlargement and an area of decreased attenuation *(arrows)*. After antimicrobial therapy, a follow-up scan showed complete regression of these findings.

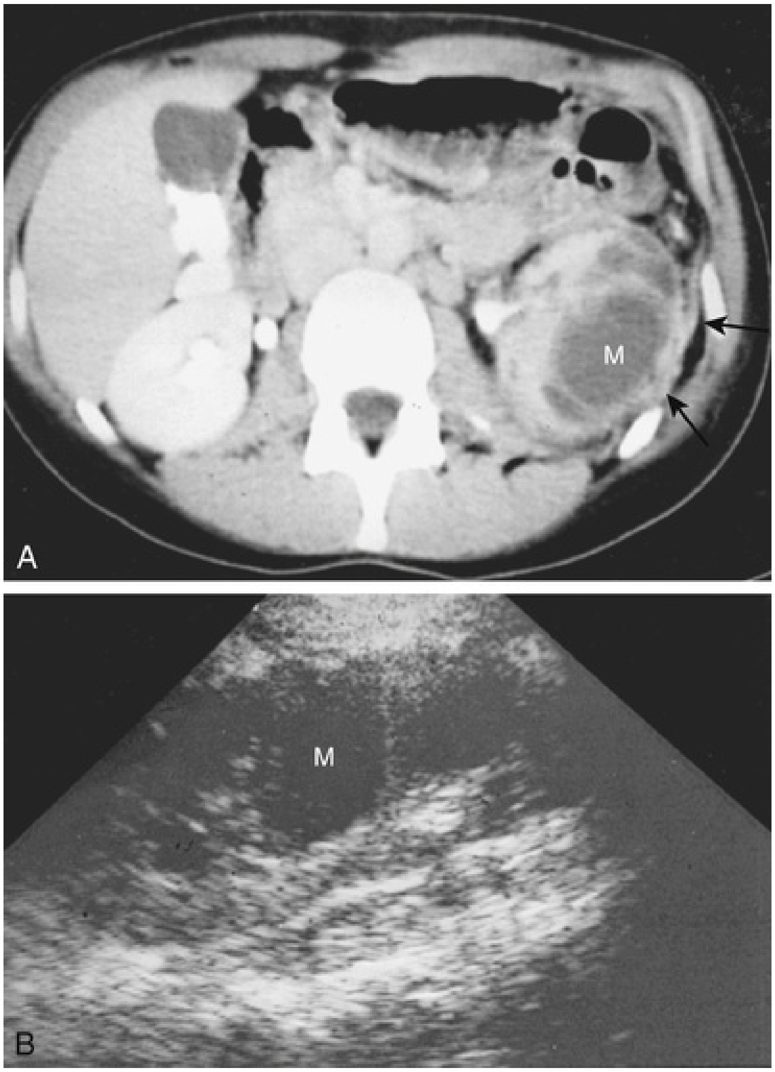

FIG. 55.30 Chronic renal abscess. (A) Enhanced computed tomography scan shows an irregular septated low-density mass *(M)* extensively involving the left kidney. Note thickening of perinephric fascia *(arrows)* and extensive compression of the renal collecting system. Findings are typical of renal abscess. (B) Ultrasound longitudinal image demonstrates a septated hypoechoic mass *(M)* occupying much of the renal parenchymal volume.

Radionuclide imaging with gallium or indium is sometimes useful in evaluating patients with renal abscesses (see previous sections).

Management.

Although the classic treatment for an abscess has been percutaneous or open incision and drainage, there is good evidence that use of IV antimicrobial agents and careful observation of a small abscess less than 3 cm or even 5 cm in a clinically stable patient is appropriate. Antibiotics, if

begun early enough in the course of the process, may obviate surgical procedures (Hoverman et al., 1980; Levin et al., 1984; Shu et al., 2004). **CT- or ultrasound-guided needle aspiration may be necessary to differentiate an abscess from a hypervascular tumor.** Aspirated material should be cultured and appropriate antimicrobial therapy instituted on the basis of the findings.

All patients should be immediately started on IV antibiotic therapy. The selection of empirical antimicrobial therapy is dependent on the presumed source of the infection and the resistance patterns within the hospital. When hematogenous dissemination is suspected, the pathogenic organism most frequently is penicillin-resistant *Staphylococcus,* and the antimicrobial of choice therefore is a penicillinase-resistant penicillin (Schiff et al., 1977). If a history of penicillin hypersensitivity is present, the recommended drug is vancomycin. Cortical abscesses that occur in the abnormal urinary tract are associated with more typical gram-negative pathogens secondary to ascending infection and should be treated empirically with IV third-generation cephalosporins, antipseudomonal penicillins, or aminoglycosides until specific therapy can be instituted. Patients should have serial examinations with ultrasonography or CT until the abscess resolves. The radiographic evolution or resolution of the abscesses typically further dictates clinical management. The suspicion of misdiagnosis or an uncontrolled infection with the development of perinephric abscess or infection with an organism resistant to the antimicrobial agents used in therapy should be suspected with worsening clinical picture.

After patients are started on IV antibiotic therapy and there is radiographic confirmation of abscess, the size of the abscess typically dictates management. Abscesses 3 cm or less can be managed with antibiotics alone (Lee et al., 2010; Shu et al., 2004; Siegel et al., 1996). In a series from South Korea of 49 patients with normal urinary tracts and abscesses smaller than 5 cm, there was 100% resolution of abscesses confirmed with CT scan with antibiotics alone (Lee et al., 2010).

Although fewer data exist for patients with obstruction or anomalous urinary tracts, **abscesses 3 to 5 cm in diameter should be conservatively managed initially in the setting of stable clinical parameters.** We suggest following the clinical course and size of the abscess radiographically to assess for improvement. Should the patient progress, percutaneous drainage should be considered. Abscesses of all sizes in immunocompromised hosts or those that do not respond to antimicrobial therapy should be drained percutaneously (Fernandez et al., 1985; Fowler and Perkins, 1994; Siegel et al., 1996).

However, percutaneous drainage remains the first-line procedure of choice for most renal abscesses larger than 5 cm in diameter. Typically, abscesses of this size require multiple drains, multiple drain manipulations, or eventual surgical washout and potential nephrectomy (Siegel et al., 1996).

Infected Hydronephrosis and Pyonephrosis

***Infected hydronephrosis* is bacterial infection in a hydronephrotic kidney. The term *pyonephrosis* refers to infected hydronephrosis associated with suppurative destruction of the parenchyma of the kidney, in which there is total or nearly total loss of renal function** (Fig. 55.31). Where infected hydronephrosis ends and pyonephrosis begins is difficult to determine clinically. Rapid diagnosis and treatment of pyonephrosis are essential to avoid permanent loss of renal function and to prevent sepsis.

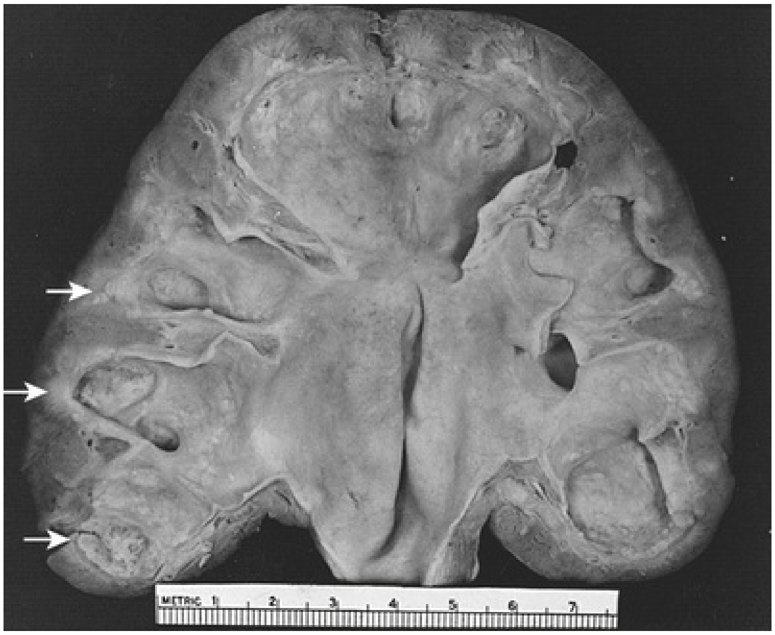

FIG. 55.31 Pyonephrosis: gross specimen. The kidney shows marked thinning of the renal cortex and medulla, suppurative destruction of the parenchyma *(arrows),* and distention of the pelvis and calyces. Previous incision released a large quantity of purulent material. The ureter showed obstruction distal to the point of section.

Clinical Presentation.

The patient is usually very ill, with high fever, chills, flank pain, and

tenderness. Occasionally, however, a patient may have only an elevated temperature and a complaint of vague gastrointestinal discomfort. A previous history of urinary tract calculi, infection, or surgery is common. **Bacteriuria may not be present if the ureter is completely obstructed.**

Radiologic Findings.

The ultrasonographic diagnosis of infected hydronephrosis depends on demonstration of internal echoes within the dependent portion of a dilated pyelocalyceal system. CT is nonspecific but may show thickening of the renal pelvis, stranding of the perirenal fat, and a striated nephrogram. Ultrasonography demonstrates hydronephrosis and fluid debris levels within the dilated collecting system (Corriere and Sandler, 1982; Fig. 55.32A). The diagnosis of pyonephrosis is suggested if focal areas of decreased echogenicity are seen within the hydronephrotic parenchyma.

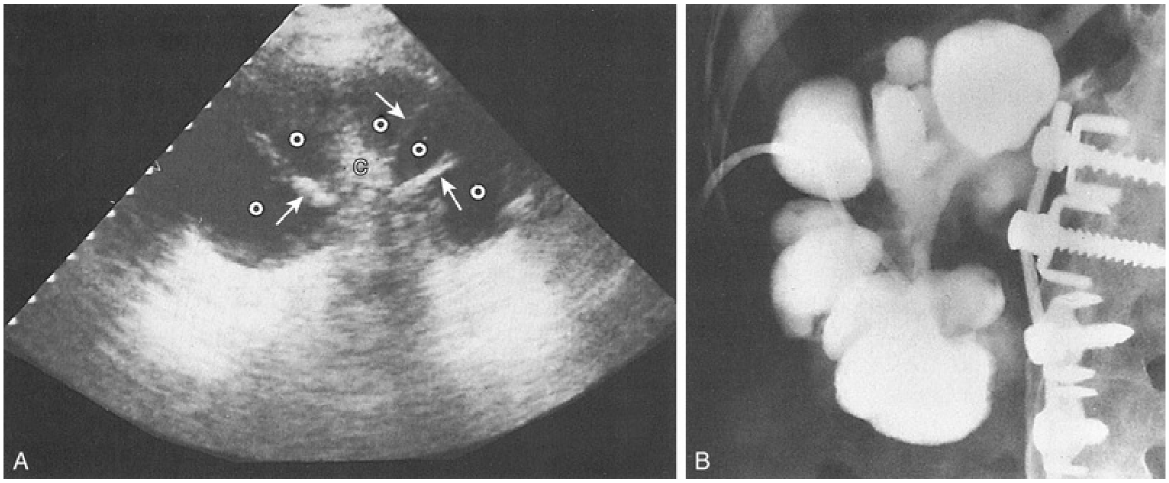

FIG. 55.32 Pyonephrosis. (A) Longitudinal ultrasound image of the right kidney demonstrates echogenic central collecting complex (C) with radiating echogenic septa *(arrows)* and thinned hypoechoic parenchyma. Multiple dilated calyces *(o)* with diffuse low-level echoes are seen. (B) Antegrade pyelogram performed through a percutaneous nephrostomy catheter correlates well with the ultrasound image. Dilated pus-filled calyces are demonstrated. The renal pelvis is obliterated by chronic scarring and stone disease. The kidney did not regain function. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

Management.

Once the diagnosis of pyonephrosis is made, the treatment is initiated with appropriate antimicrobial drugs and drainage of the infected pelvis. A ureteral catheter can be passed to drain the kidney, but if the obstruction prevents this, a percutaneous nephrostomy tube should be placed (Camunez et al., 1989; Fig. 55.32B). When the patient becomes hemodynamically stable, other procedures are usually needed to identify and treat the source of the obstruction.

Perinephric Abscess

A perinephric abscess extends beyond the renal capsule but is contained by Gerota fascia and **usually results from rupture of an acute cortical abscess into the perinephric space,** extravasated infected urine from obstruction**, or from hematogenous seeding from sites of infection.** Patients with pyonephrosis, particularly when a calculus is present in the kidney, are susceptible to perinephric abscess formation. **Diabetes mellitus is present in approximately one-third of patients with perinephric abscess** (Edelstein and McCabe, 1988; Meng et al., 2002). **In about one-third of the cases, perinephric abscess is caused by hematogenous spread, usually from sites of skin infection** (Gardiner et al., 2011). A perirenal hematoma can become secondarily infected by the hematogenous route or by direct extension of a primary renal infection. When a perinephric infection ruptures through the Gerota fascia into the pararenal space, the abscess becomes paranephric. Paranephric abscesses may also result from infectious disorders of the bowel, pancreas, or pleural cavity. Conversely, perinephric or psoas abscess may be the result of bowel perforation, Crohn disease, or spread of osteomyelitis from the thoracolumbar spine. *E. coli, Proteus,* and *S. aureus* account for most infections.

Clinical Presentation.

The onset of symptoms is typically insidious. Symptoms are present for more than 5 days in most patients with perinephric abscess compared with only about 10% of patients with pyelonephritis. The clinical presentation may be similar to that of pyelonephritis; however, more than one-third of patients may be afebrile. An abdominal or flank mass can be felt in about half of the cases; costovertebral angle tenderness is typically present. Psoas abscess should be suspected if the patient has a limp and flexion and external rotation of the ipsilateral hip. Laboratory features include leukocytosis, elevated levels of serum creatinine, and pyuria in more than 75% of cases. Edelstein (1988) showed that results of urine cultures predicted perinephric abscess isolates in only 37% of cases; a blood culture, particularly with multiple organisms, was often indicative of perinephric abscess but identified all organisms in only 42% of cases. Meng et al. (2002) showed that roughly 75% of patients had a positive culture. Urine was statistically significantly more sensitive than blood and abscess fluid collection in their study. **Therefore caution should be exercised when choosing therapy based on the results of urine and blood cultures because data may sometimes be inadequate. Pyelonephritis usually responds within 4 to 5 days of appropriate antimicrobial therapy; perinephric abscess does not. Thus perinephric abscess should be suspected in a patient with UTI and abdominal or flank mass or persistent fever after 4 days of antimicrobial therapy. Perinephric abscesses are commonly seen concomitantly with renal abscesses.**

CT is particularly valuable for demonstrating the primary abscess. In some cases, the abscess is confined to the perinephric space; however, extension to the flank or psoas muscle may occur (Fig. 55.33). CT is able to show with exquisite anatomic detail the route of spread of infection into the surrounding tissues and will demonstrate any obstruction that may be present (Fig. 55.34). This information may be helpful in planning the approach for surgical drainage. Ultrasonography demonstrates a diverse appearance ranging from a nearly anechoic mass displacing the kidney to an echogenic collection that tends to blend with normally echogenic fat within the Gerota fascia (Corriere, 1982). Occasionally, a retroperitoneal or subdiaphragmatic infection may spread to the paranephric fat that is outside this fascia. The clinical symptoms of insidious onset of fever, flank mass, and tenderness are indistinguishable from those associated with perinephric abscess. UTI, however, is absent. Ultrasonography and CT can usually delineate the abscess outside the Gerota fascia.

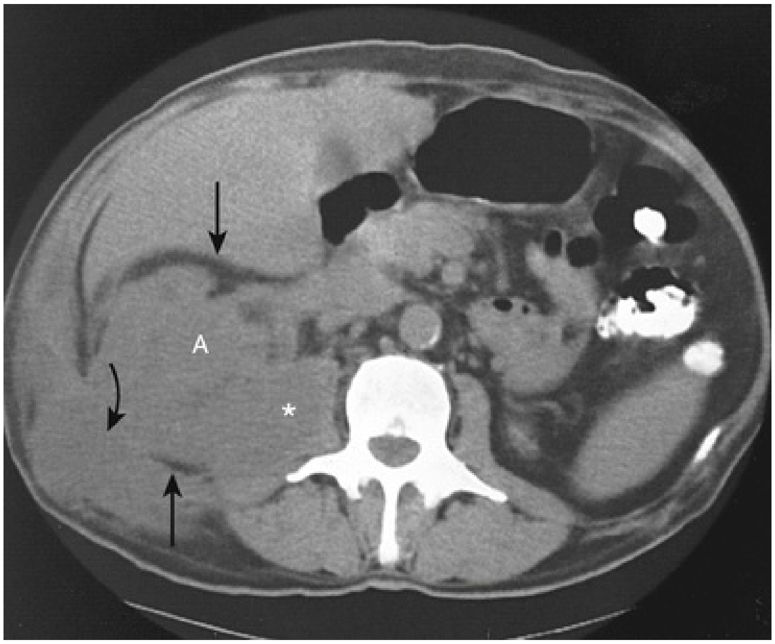

FIG. 55.33 Nonenhanced computed tomography scan through the lower pole of the right kidney (previous left nephrectomy) shows extensive perinephric abscess. Extensive abscess (A) distorts and enlarges the renal contour, infiltrates perinephric fat *(straight arrows),* and extends into the psoas muscle *(asterisk)* and the soft tissues of the flank *(curved arrow).* Also note that normal renal collecting system fat has been obliterated by the process.

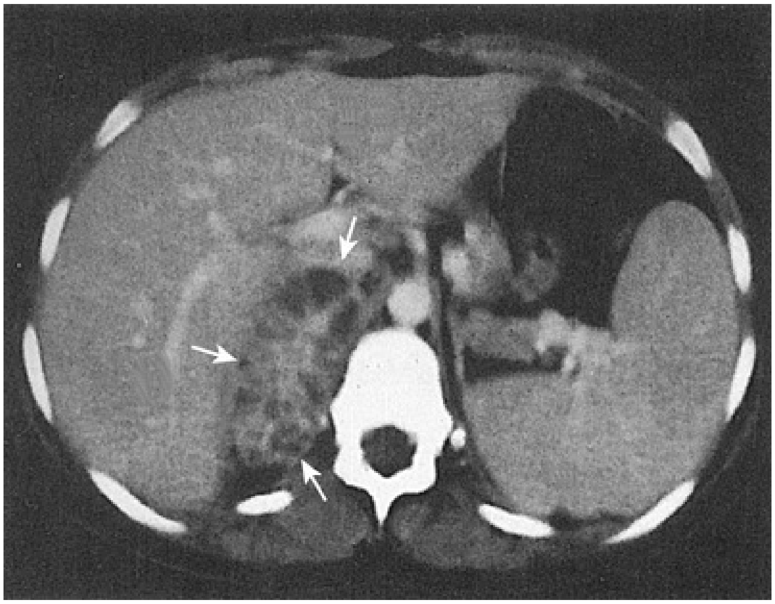

FIG. 55.34 Perinephric abscess involving the right adrenal gland. Computed tomography scan shows large right pararenal mass *(arrows)* with multiple low-density areas within. At surgery, a large pararenal

abscess with extensive involvement of the right adrenal was found. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

Improved imaging techniques have decreased the mortality rate of 40% to 50% in early series to roughly 12%, but there is still an average of 3.4 days' lag time before appropriate diagnosis in a contemporary series (Meng et al., 2002). Only 35% of patients were correctly diagnosed on presentation in the Meng series, and this lag time contributed to mortality in nearly all patients in that series. Having an appropriate threshold for imaging will continue to improve the rate of correct diagnoses.

Management.

Antimicrobial agents should be immediately started upon diagnosis of perinephric abscess. Gram stain identifies the pathogenesis and guides antimicrobial therapy. An aminoglycoside together with an antistaphylococcal agent, such as methicillin or oxacillin, should be started immediately. If the patient has a penicillin hypersensitivity, cephalothin or vancomycin may be used.

In addition to controlling sepsis and preventing further spread of infection, Meng et al.'s series of 25 patients suggests that, for small perinephric abscesses (<3 cm), antibiotics alone can appropriately treat immune-competent patients (Meng et al., 2002)**. Eight out of the 10 patients treated with antibiotics alone had full resolution after a mean of 10 days in the hospital. The average size of abscess treated was 1.8 cm. Siegel et al.** (1996) **also showed good resolution of perinephric abscesses less than 3 cm, with cure seen in all five patients in their series.**

For larger collections or those not responsive to initial antibiotic therapy, intervention is the next step in treatment. **Surgical drainage, or nephrectomy if the kidney is nonfunctioning or severely infected, was the classic treatment for perinephric abscesses. However, with the advent of the field of interventional radiology and improvements in percutaneous drainage techniques, renal ultrasonography and CT- or ultrasound-guided percutaneous aspiration and drainage of perirenal collections is now a good option for therapy.** In Meng's study, 11 of the 25 patients had percutaneous drainage in addition to antibiotics (Meng et al., 2002). The mean abscess size was 11 cm and the mean time to resolution was 25 days. Four of these patients eventually required open surgical exploration and drainage. All removed kidneys demonstrated hallmarks of minimal function. **Unlike in renal abscesses, early drainage of abscesses greater than 3 cm in diameter is recommended.**

Once the perinephric abscess has been drained, the underlying problem must be addressed. Some conditions such as renal cortical abscess or enteric communication require prompt attention. Nephrectomy for pyonephrosis may be performed concurrent with drainage of the perinephric abscess if the patient's condition is good. In other instances it is best to drain the perinephric abscess first and correct the underlying problem or perform a nephrectomy when the patient's condition has improved. Meng's series of 11 patients with abscesses greater than 11 cm had a roughly 33% need for nephrectomy (Meng et al., 2002). Although this is a high number in patients who are likely diabetic, whereas the nephron-sparing approach is ideal, it is decidedly lower than the historical nephrectomy rate, likely secondary to more successful percutaneous drainage rates. In three of their patients with small perinephric abscesses and hydronephrosis, antibiotics and drainage of the obstructed urinary system led to cure.

Perinephric Abscess Versus Acute Pyelonephritis.

Once again, the greatest obstacle to the treatment of perinephric abscess is the delay in diagnosis. **In the series by Thorley et al. (1974), a common misdiagnosis was acute pyelonephritis; Meng's study showed a similar delay of roughly 3 to 4 days in appropriate diagnosis in a modern study** (Meng et al., 2002). **Thorley's study found that two factors differentiated perinephric abscess and acute pyelonephritis: (1) most patients with uncomplicated pyelonephritis were symptomatic for less than 5 days before hospitalization, whereas most with perinephric abscesses were symptomatic for longer than 5 days; and (2) no patient with acute pyelonephritis remained febrile for longer than 4 days once appropriate antimicrobial agents were started. All patients with perinephric abscesses had a fever for at least 5 days, with a median of 7 days. Similar results were noted by Fowler and Perkins (1994).**

Patients with polycystic renal disease who undergo hemodialysis may be particularly susceptible to the progression from acute UTIs to perinephric abscess. Of 445 patients undergoing chronic hemodialysis at the Regional Kidney Disease Program in Minneapolis, 5.4% had polycystic kidney disease and 33.3% developed symptomatic UTIs (Sweet and Keane, 1979). Eight (62.5%) developed perinephric abscesses, and three of these patients died. According to the investigators, all UTIs, even those that progressed to perinephric abscesses, were promptly treated with appropriate antimicrobial agents, and all patients in this group became afebrile and asymptomatic when the agents were stopped. However, later, after various times, symptoms attributable to perinephric abscess developed in eight of the patients. The mechanism of this process is not clear, but the limited bioavailability of some antimicrobial agents in cysts is variable and could contribute to the progression of renal infection.

Chronic Pyelonephritis

In patients without underlying renal or urinary tract disease, chronic pyelonephritis secondary to UTI is a rare disease and an even more rare cause of chronic renal failure. In patients with underlying functional or structural urinary tract abnormalities, however, chronic renal infection can cause significant renal impairment. Thus it is essential that appropriate studies be used to diagnose, localize, and treat chronic renal infection.

The prevalence of chronic pyelonephritis has also been assessed in patients undergoing dialysis for end-stage renal disease. Despite a 2% to 5% prevalence of bacteriuria in women, pyelonephritis uncomplicated by obstruction or urinary tract malformation does not cause end-stage renal disease. Schechter et al. (1971) analyzed the cause for renal failure in 170 patients referred to them for dialysis. Chronic pyelonephritis was the primary cause of end-stage renal disease in 22 (13%) but was usually associated with an underlying structural defect. Unequivocal nonobstructive chronic pyelonephritis was not found. Symptomatic infections tended to occur before the onset of azotemia in most patients with chronic pyelonephritis. Similarly, Huland and Busch (1982) evaluated 161 patients with end-stage renal disease and found that 42 had chronic pyelonephritis. However, in addition to a history of UTIs, these 42 patients had complicating defects, such as VUR, analgesic abuse, nephrolithiasis, or obstruction. Nonobstructive uncomplicated UTI alone was never found to be the cause of renal insufficiency. Thus, using end-stage renal disease seen at autopsy or at the dialysis clinic as an indicator, the occurrence of uncomplicated chronic bacterial pyelonephritis is rare.

In addition, the role of bacterial infection in development of chronic renal disease can be assessed in patients with renal interstitial and tubular damage similar to that which has classically been called chronic pyelonephritis. The frequency with which various potential causes of interstitial damage are operative in patients with interstitial nephritis was assessed by Murray and Goldberg (1975). These investigators not only concluded that UTI is rarely the sole cause of chronic renal disease in the adult but also observed that 89% of their azotemic patients had a readily identifiable primary cause of their interstitial nephritis. Thus, when patients with a clinical diagnosis of chronic interstitial nephritis are selected as the starting point, it is easy to associate many factors with this disease, but UTI does not seem to be one of them.

Clinical Presentation.

There are no symptoms of chronic pyelonephritis until it produces renal insufficiency, and then the symptoms are similar to those of any other form of chronic renal failure. If a patient's chronic pyelonephritis is thought to be a result of many episodes of acute pyelonephritis, a history of intermittent symptoms of fever, flank pain, and dysuria may be elicited. Similarly, urinary findings and the presence of renal infection correlate poorly. Bacteriuria and pyuria, the hallmarks of UTI, are not predictive of renal infection. Conversely, patients with significant renal infection may have sterile urine if the ureter draining the kidney is obstructed or the infection is outside of the collecting system.

The pathologic and radiologic criteria for diagnosing renal infection may also be misleading. Asscher (1980) has tabulated eight long-term follow-up studies from the literature on kidneys of adults with UTIs. The data from these reports on 901 patients show that bacteriuria present in otherwise healthy adults for long periods may be associated with nonexistent or extremely minimal evidence of kidney damage. Conversely, patients who have chronic pyelonephritis may have negative urine cultures.

Radiologic Findings.

The diagnosis of chronic pyelonephritis can be made with the greatest confidence on the basis of pyelographic findings. The essential features are asymmetry and irregularity of the kidney outlines, blunting and dilation of one or more calyces, and cortical scars at the corresponding site (Fig. 55.35). In addition to stones, obstruction, tuberculosis, and analgesic nephritis with papillary necrosis (which can be readily excluded by history), chronic pyelonephritis can also produce a localized scar over a deformed calyx. In advanced pyelonephritis, calyceal distortion and irregularity together with cortical scars complete the picture. Calyceal stones and reflux nephropathy may produce a scarred kidney that is indistinguishable from post-pyelonephritis findings. Regardless of the cause of chronic pyelonephritis, CT findings will be consistent with atrophy, cortical/parenchymal thinning, calyceal clubbing, and possible hypertrophy of residual normal tissue and asymmetry (Craig et al., 2008). Fig. 55.36 (D'Souza et al., 1995) showed a linear relationship between renal parenchymal volume loss and function decline as assessed by DMSA scan. Hodson and Wilson (1965) pointed out that renal infarction, an extremely rare condition, may closely resemble pyelonephritic scars but that the renal pyramid remains with renal infarction in contradistinction to pyelonephritis.

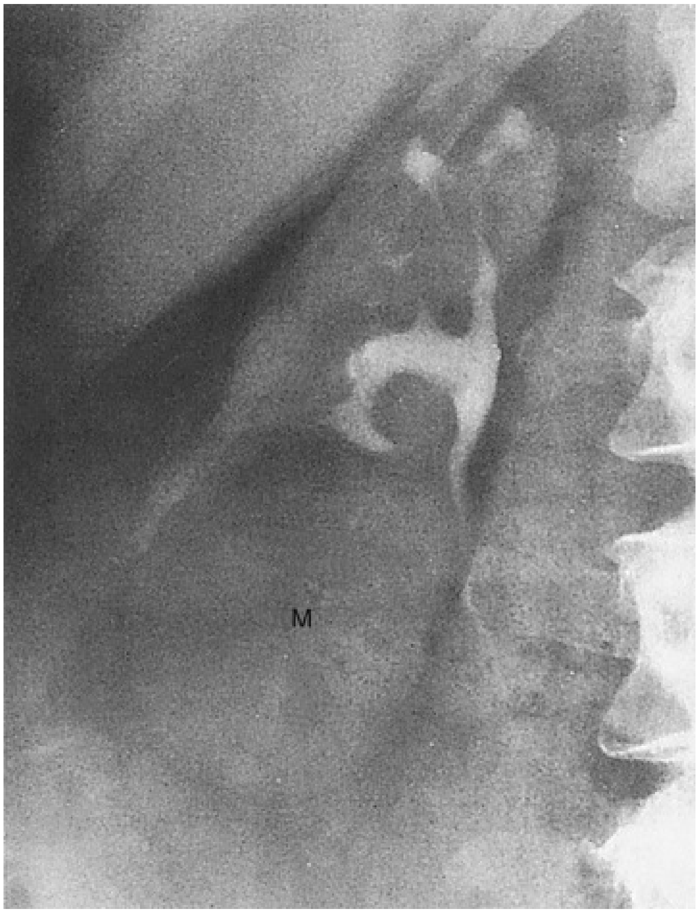

FIG. 55.35 Chronic pyelonephritis. Ten-minute excretory urogram demonstrates irregular renal outline with upper pole parenchymal atrophy. Note significant loss of renal cortical thickness over blunted and dilated calyces. Lower pole mass *(M)* is a simple cyst. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

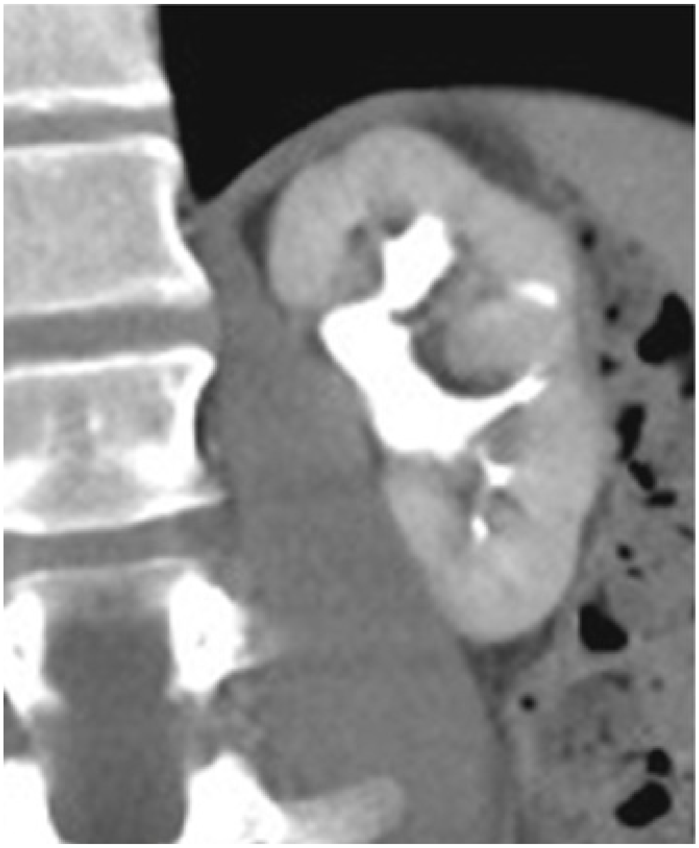

FIG. 55.36 Computed tomography of chronic pyelonephritis. There are cortical scars and blunted calyces.

Pathology.

In chronic pyelonephritis, the gross kidney is often diffusely contracted, scarred, and pitted. The scars are Y-shaped, flat, broad-based depressions with red-brown granular bases. The scarring is often polar with underlying calyceal blunting. The parenchyma is thin, and the corticomedullary demarcation is lost. **Histologic changes are patchy.** There is usually an interstitial infiltrate of lymphocytes, plasma cells, and occasional polymorphonuclear cells. Portions of the parenchyma may be replaced by fibrosis, and, although glomeruli may be preserved, periglomerular fibrosis is often seen. In some affected areas, glomeruli may be completely fibrosed and tubules atrophied. Leukocyte and hyaline casts are sometimes present in the tubules; the latter may cause resemblance to the thyroid colloid, hence the description *renal thyroidization* (Braude, 1973). In general, the changes are nonspecific; they also may be seen in toxic exposures, postobstructive atrophy, hematologic disorders, postirradiation nephritis, ischemic renal disease, and nephrosclerosis. **The pathology of stone-**

induced scars and reflux-induced scars may be identical.

Management.

Management of radiographic evidence of pyelonephritis should be directed at treating infection if present, preventing future infections, and monitoring and preserving renal function. The treatment of existing infection must be based on careful antimicrobial susceptibility tests and selection of drugs that can achieve bactericidal concentrations in the urine and yet are not nephrotoxic. Achievement of acceptable bactericidal levels of a drug in the urine of a patient with chronic pyelonephritis may be difficult because the diminished concentrating ability of pyelonephritis may impair excretion and concentration of the antimicrobial agent. The duration of antimicrobial therapy is often prolonged to maximize the chance of cure. With patients in whom renal damage develops or progresses in the presence of UTI, the working hypothesis should be that there is an underlying renal, usually papillary, lesion or underlying urologic condition, such as obstruction or calculus, which has increased susceptibility to renal damage. Appropriate nephrologic and urologic evaluation should be undertaken to identify and, if possible, correct these abnormalities.

Bacterial “Relapse” From a Normal Kidney

The concept that bacteria persist in the renal parenchyma between bacteriuric episodes and cause “relapsing” UTIs was based on a study by Turck et al. (1968) that suggested that bacterial persistence could be recognized by simply identifying two consecutive recurrent infections with the same organism. Unfortunately, this study did not indicate whether the urine was cultured during therapy to ensure that the original infection had actually been eradicated. It is possible that some of these so-called relapses were in fact unresolved initial infections and that ureteral edema associated with catheterization may have impeded clearance of the initial infecting strain.

Subsequent studies summarized by Stamey (1980) **and Forland et al.** (1977) **have shown that, in a normal urinary tract, recurrent infections are not caused by relapse from bacterial persistence in the kidney.** With ureteral catheterization techniques Cattell et al. (1973) localized the site of bacteriuria in 42 patients who had follow-up for 6 months after therapy. He analyzed the response to antimicrobial therapy of 2 weeks’ duration. Of the 26 patients who were cured of their initial infection, 16 had recurrence with the same organism, 8 had upper tract infections, and 8 had bladder bacteriuria.

Most of the changes of chronic pyelonephritis seem to occur in infancy, probably because the growing kidney is most susceptible to scarring. A review that examined the long-term effect of UTIs in adults concluded that renal damage is rare in nonobstructive UTIs (Stamey, 1980), but it does occur (Bailey et al., 1969; Davidson and Talner, 1978; Davies et al., 1972; Feldberg, 1982).

The association between hypertension and the pyelonephritic kidney has been addressed by Pfau and Rosenmann (1978), who concluded that the association of chronic pyelonephritis and hypertension is usually coincidental. Their conclusion agrees with that of a study by Parker and Kunin (1973) that examined 74 women who had been admitted to the hospital 10 to 20 years previously for pyelonephritis. Only 14.5% of these women had hypertension, a rate similar to that found in a random female population of the same age.

Infectious Granulomatous Nephritis

Xanthogranulomatous Pyelonephritis

Xanthogranulomatous pyelonephritis (XGP) is a rare, severe, chronic renal infection typically resulting in diffuse renal destruction. Most cases are unilateral and result in a nonfunctioning, enlarged kidney associated with obstructive uropathy secondary to nephrolithiasis. XGP is characterized by accumulation of lipid-laden foamy macrophages. It begins within the pelvis and calyces and subsequently extends into and destroys renal parenchymal and adjacent tissues. It has been known to imitate almost every other inflammatory disease of the kidney, as well as renal cell carcinoma, on radiographic examination (Malek and Elder, 1978; Tolia et al., 1980). In addition, the microscopic appearance of XGP has been confused with clear cell adenocarcinoma of the kidney on frozen section and has led to radical nephrectomy (Anhalt et al., 1971; Flynn et al., 1979; Lorentzen and Nielsen, 1980; Malek and Elder, 1978; Tolia et al., 1980). The entity is uncommon and is found in only about 0.6% (Malek et al., 1972) to 1.4% (Ghosh, 1955) of patients with renal inflammation who are evaluated pathologically.

Pathogenesis.

The primary factors involved in the pathogenesis of XGP are nephrolithiasis, obstruction, and infection (Gregg et al., 1999). Nephrolithiasis has been noted in as many as 83% of the patients in various series;

approximately half of the renal stones have been of the staghorn type (Chuang et al., 1992; Nataluk et al., 1995; Parsons et al., 1983). It has been proposed clinically and demonstrated experimentally that primary obstruction followed by infection with *E. coli* can lead to tissue destruction and collections of lipid material by macrophages (Povysil and Konickova, 1972). These macrophages (xanthoma cells) are distributed in sheets around parenchymal abscesses and calyces and are intermixed with lymphocytes, giant cells, and plasma cells. The bacteria appear to be of low virulence because spontaneous bacteremia has rarely been described. Other possible interrelated factors include venous occlusion and hemorrhage, abnormal lipid metabolism, lymphatic blockage, failure of antimicrobial therapy in UTI, altered immunologic competence, and renal ischemia (Friedenberg and Spjut, 1963; Goodman et al., 1979; McDonald, 1981; Mering et al., 1973; Tolia et al., 1981). The concept that XGP is related to incomplete bacterial degradation and altered host response has received mixed support (Khalyl-Mawad et al., 1982; Nielsen and Lorentzen, 1981). Thus it appears that there is probably no single factor instrumental in the pathogenesis of this disease. Rather, there is an inadequate host acute inflammatory response within an obstructed, ischemic, or necrotic kidney.

Pathology.

The kidney is usually massively enlarged and has a normal contour. XGP may be diffuse, as in approximately 80% of the patients, or segmental. In the diffuse form of the disease, the entire kidney is involved, whereas in segmental XGP, only the parenchyma surrounding one or more calyces or one pole of a duplicated collecting system is involved. On sectioning, the kidney usually demonstrates nephrolithiasis and peripelvic fibrosis. The calyces are dilated and filled with purulent material, but fibrosis surrounding the pelvis usually prevents dilation. The papillae are often destroyed by papillary necrosis (Goodman et al., 1979). In advanced stages of the disease, multiple parenchymal abscesses are filled with viscous pus and lined by yellowish tissue (Fig. 55.37A). The cortex is often thin and replaced by xanthogranulomatous tissue. The capsule is often thickened, and extension of the inflammatory process into the perinephric or paranephric space is common (Goodman et al., 1979; Gregg et al., 1999; McDonald, 1981).

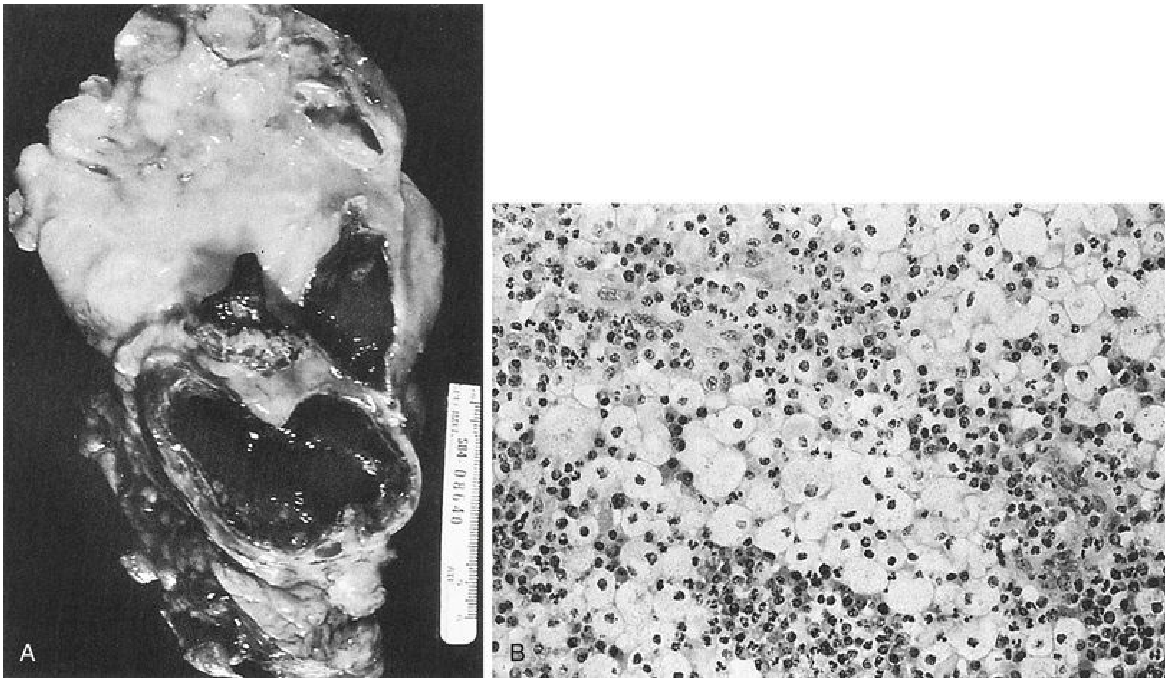

FIG. 55.37 Xanthogranulomatous pyelonephritis. (A) Gross specimen. Kidney is massively enlarged, measuring 23 × 12 cm; the normal architecture is replaced by a shaggy yellow upper pole mass corresponding to xanthogranulomatous inflammation and numerous distorted and dilated calyces. (B) Microscopically, the shaggy yellow tissue is composed primarily of lipid-laden histiocytes mixed with other inflammatory cells. (From Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology*, Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.)

On microscopic examination, the yellowish nodules that line the calyces and surround the parenchymal abscesses contain dark sheets of lipid-laden macrophages (foamy histiocytes with small, dark nuclei and clear cytoplasm) intermixed with lymphocytes, giant cells, and plasma cells (Fig. 55.37B). Xanthogranulomatous cells are not specific to XGP but may be present anywhere inflammation or obstruction coexists. The origin of the fatty substance is disputed. Cholesterol esters that make up a part of the lipid may be derived from lysis of erythrocytes after hemorrhage (Saeed and Fine, 1963).

Clinical Presentation.

XGP should be suspected in patients with UTIs and a unilateral enlarged nonfunctioning or poorly functioning kidney with a stone or a mass lesion indistinguishable from malignant tumor. Most patients experience flank pain (69%), fever and chills (69%), and persistent bacteriuria (46%) (Malek and Elder, 1978). **Additional vague symptoms, such as malaise, may be**

present. On physical examination, 62% of the patients had a flank mass and 35% had previous calculi (Malek and Elder, 1978). Less commonly, hypertension, hematuria, or hepatomegaly is the presenting complaint. The medical history is often positive for UTIs and urologic instrumentation (Eastham et al., 1994; Flynn et al., 1979; Goodman et al., 1979; Grainger et al., 1982; Malek and Elder, 1978; Nataluk et al., 1995; Petronic et al., 1989; Yazaki et al., 1982). People with diabetes also appear to be at greater risk of developing the disease (Eastham et al., 1994). Although it may occur at any age, the peak incidence of XGP is in the fifth to the seventh decade. Women are more commonly affected than men. There is no predilection for either kidney.

Bacteriology and Laboratory Diagnosis.

Although review of the literature shows *Proteus* to be the most common organism involved with XGP (Anhalt et al., 1971; Tolia et al., 1981), *E. coli* is also common. The prevalence of *Proteus* organisms may reflect their association with stone formation and subsequent chronic obstruction and irritation. Malek and Elder (1978), in their analysis of 26 cases, found that renal tissue cultures grew bacteria in 22 of 23 cases. Anaerobes also have been cultured (Malek and Elder, 1978).

Approximately 10% of patients have mixed cultures. About one-third of patients have no growth in their urine, probably because many patients have recently taken or are taking antimicrobial agents when cultures are obtained. The infecting organism may be revealed only by tissue cultures obtained during surgery. Urinalysis usually shows pus and protein. In addition, blood tests often reveal anemia and may show hepatic dysfunction in up to 50% of the patients (Malek and Elder, 1978).

XGP is almost always unilateral; therefore azotemia or frank renal failure is uncommon (Goodman, et al. 1979; Gregg et al., 1999).

CT is probably the most useful radiologic technique in evaluating patients with XGP (Fig. 55.38). Fifty to eighty percent of patients show the classic triad of unilateral renal enlargement with little or no function and a large calculus in the renal pelvis (Elder, 1984)**. CT usually demonstrates a large, reniform mass with the renal pelvis tightly surrounding a central calcification but without pelvic dilatation** (Goldman et al., 1984; Hartman, 1985; Solomon et al., 1983). Renal parenchyma is replaced by multiple water-density masses representing dilated calyces and abscess cavities filled with varied amounts of pus and debris. On enhanced scans, the walls of these cavities demonstrate a prominent blush because of the abundant vascularity within the granulation tissue. The cavities themselves, however, fail to enhance, whereas tumors and other inflammatory lesions usually do. The CT scan is particularly helpful in demonstrating the extent of renal involvement and may indicate whether adjacent organs or the abdominal wall are involved by XGP (Eastham et al., 1994; Kaplan et al., 1997).

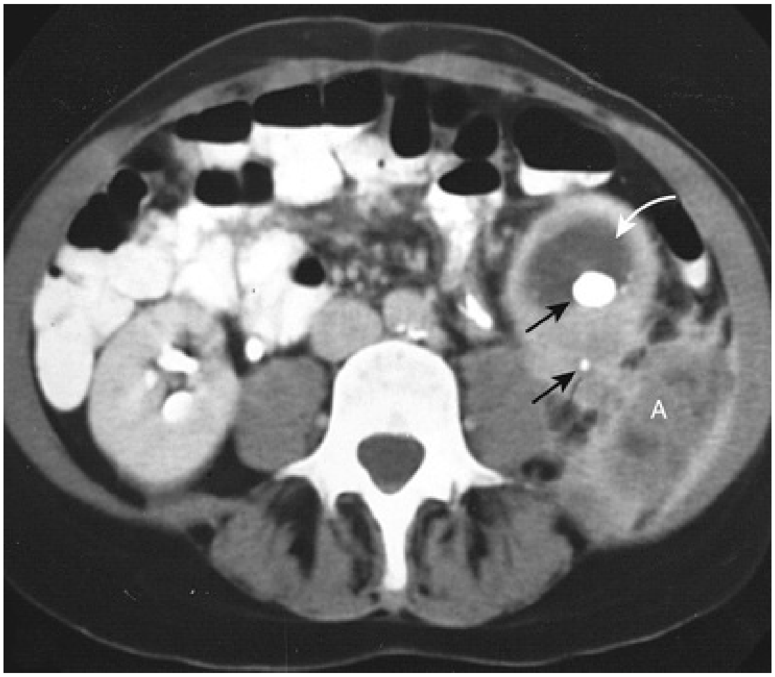

FIG. 55.38 Xanthogranulomatous pyelonephritis. Enhanced computed tomography scan shows collecting system and parenchymal calculi *(straight black arrows)* with lower pole pyonephrosis *(curved white arrow)* and an irregular, predominantly low-density perinephric abscess *(A)* extending into the soft tissues of the flank.

Ultrasonography usually demonstrates global enlargement of the kidney (Merenich and Popky, 1991). The normal renal architecture is replaced by multiple hypoechoic fluid-filled masses that correspond to debris-filled, dilated calyces or foci of parenchymal destruction (Fagerholm, 1983; Hartman et al., 1984). With focal involvement, a solid mass involving a segment of the kidney is sometimes called tumefactive xanthogranulomatous pyelonephritis. There may or may not be an associated calculus in the collecting system or ureter. Renal cell carcinoma and other solid renal lesions must be considered in the differential diagnosis (Elder, 1984).

Radionuclide renal scanning using ^{99m}Tc-DMSA is used to confirm and quantify the differential lack of function in the involved kidney (Gregg et al., 1999). MRI has not yet superseded CT in the evaluation of renal inflammation, but it provides some advantages in delineating extrarenal extension of inflammation (Soler et al., 1997). Lesions of XGP may appear as cystic foci of intermediate intensity signal on T1-weighted images and hyperintensity on T2-weighted images. Arteriography shows hypervascular areas, but there may be some hypovascular areas (Malek and Elder, 1978, Tolia et al., 1981; Van Kirk et al., 1980). Therefore radiologic studies, although distinctive, often cannot be used to differentiate between XGP and renal cell carcinoma.

Differential Diagnosis.

Diagnosis of segmental XGP without calculi may be difficult. XGP in association with massive pelvic dilation cannot be distinguished from pyonephrosis. When XGP occurs within a small contracted kidney, the radiographic findings are nonspecific and nondiagnostic. Renal parenchymal malacoplakia may show renal enlargement and multiple inflammatory masses replacing the normal renal parenchyma, but calculi are usually not present. Renal lymphoma may be associated with multiple hypoechoic masses surrounding the contracted, nondilated pelvis, but lymphoma is usually clinically obvious, and renal involvement is usually bilateral and not associated with calculi (Hartman et al., 1984).

Management.

The primary obstacle to the correct treatment of XGP is incorrect diagnosis. Today with CT technology, the diagnosis of XGP is made preoperatively nearly 90% of the time (Eastham et al., 1994; Nataluk et al., 1995). Antimicrobial therapy may be necessary to stabilize the patient preoperatively, and, **occasionally, long-term antimicrobial therapy will eradicate the infection and restore renal function** (Mollier et al., 1995). Because the renal abnormality may be diagnosed preoperatively as a renal tumor and/or is diffuse, **nephrectomy is usually performed.** If localized XGP is diagnosed preoperatively or at exploration, it is amenable to partial nephrectomy (Malek and Elder, 1978; Osca et al., 1997; Tolia et al., 1980).

The lipid-laden macrophages associated with XGP, however, closely resemble clear cell adenocarcinoma and may be difficult to distinguish solely on the basis of frozen section. Furthermore, XGP has been associated with renal cell carcinoma, papillary transitional cell carcinoma of the pelvis

or bladder, and infiltrating squamous cell carcinoma of the pelvis (Pitts et al., 1981; Schoborg et al., 1980; Tolia et al., 1981); thus, if malignant renal tumor cannot be excluded, nephrectomy should be performed. When diffuse and extensive disease into the retroperitoneum exists, removal of the kidney and perinephric fat may be needed. Under these circumstances, the surgery may be difficult and may involve dissection of granulomatous tissue from the diaphragm, great vessels, and bowel (Flynn et al., 1979; Malek and Elder, 1978). It is important to remove the entire inflammatory mass because in nearly three-fourths of patients, xanthogranulomatous tissue is infected. If incision and drainage alone are performed rather than nephrectomy, the patient may continue to suffer from protracted debilitating illness and may develop a renal cutaneous fistula; an even more difficult nephrectomy will then be necessary. One early case-matched series of laparoscopic nephrectomies performed for XGP concluded that the benefits of laparoscopic surgery do not extend to the treatment of this disease (Bercowsky et al., 1999); however, a larger review of a modern XGP experience suggests that laparoscopic nephrectomy is a reasonable treatment approach (Guzzo et al., 2009; Kapoor et al., 2006; Vanderbrink et al., 2007). Some studies suggest a retroperitoneal approach laparoscopically and, if transperitoneal, the use of a hand-assist port (Tobias-Machado et al., 2005). Although feasible, removal of an XGP kidney is difficult, and high conversion rates were seen across multiple studies (Korkes et al., 2008).

Malacoplakia

Malacoplakia, from the Greek word meaning “soft plaque,” is an unusual inflammatory disease originally described to affect the bladder but has been found to affect the GU and GI tracts, skin, lungs, bones, and mesenteric lymph nodes. It is an inflammatory lesion described originally by Michaelis and Gutmann (1902). It was characterized by von Hansemann (1903) as soft, yellow-brown plaques with granulomatous lesions in which the histiocytes contain distinct basophilic lysosomal inclusion bodies or Michaelis-Gutmann bodies. Although its exact pathogenesis is unknown, malacoplakia probably results from abnormal macrophage function in response to a bacterial infection, which is most often *E. coli*.

Pathogenesis.

The pathogenesis is unknown, but several theories are popular. In 93 patients who had cultures of urine, diseased tissue, or blood, 89.4% had coliform infections (Stanton and Maxted, 1981). Moreover, 40% of the patients in this review had an immunodeficiency syndrome, autoimmune disease, carcinoma, or another systemic disorder. **This association of coliform infections and compromised health status in patients with malacoplakia is well recognized.**

It is hypothesized that bacteria or bacterial fragments form the nidus for the calcium phosphate crystals that laminate the Michaelis-Gutmann bodies. Most investigations into the pathogenesis of this disease support theories that a defect in intraphagosomal bacterial digestion accounts for the unusual immunologic response that causes malacoplakia.

Pathology.

The diagnosis is made by biopsy. The lesion is characterized by large histiocytes, known as *von Hansemann cells*, and small basophilic, extracytoplasmic, or intracytoplasmic calculospherules called *Michaelis-Gutmann bodies*, which are pathognomonic (Fig. 55.39). Electron microscopy has revealed intact coliform bacteria and bacterial fragments within phagolysosomes of the foamy-appearing malacoplakic histiocytes (Lewin et al., 1976; Stanton and Maxted, 1981). In their review of the subject, Stanton and Maxted (1981) and Esparza et al. (1989) emphasized that, although pathognomonic for the disease, Michaelis-Gutmann bodies may be absent in early malacoplakia and are not necessary for the diagnosis.

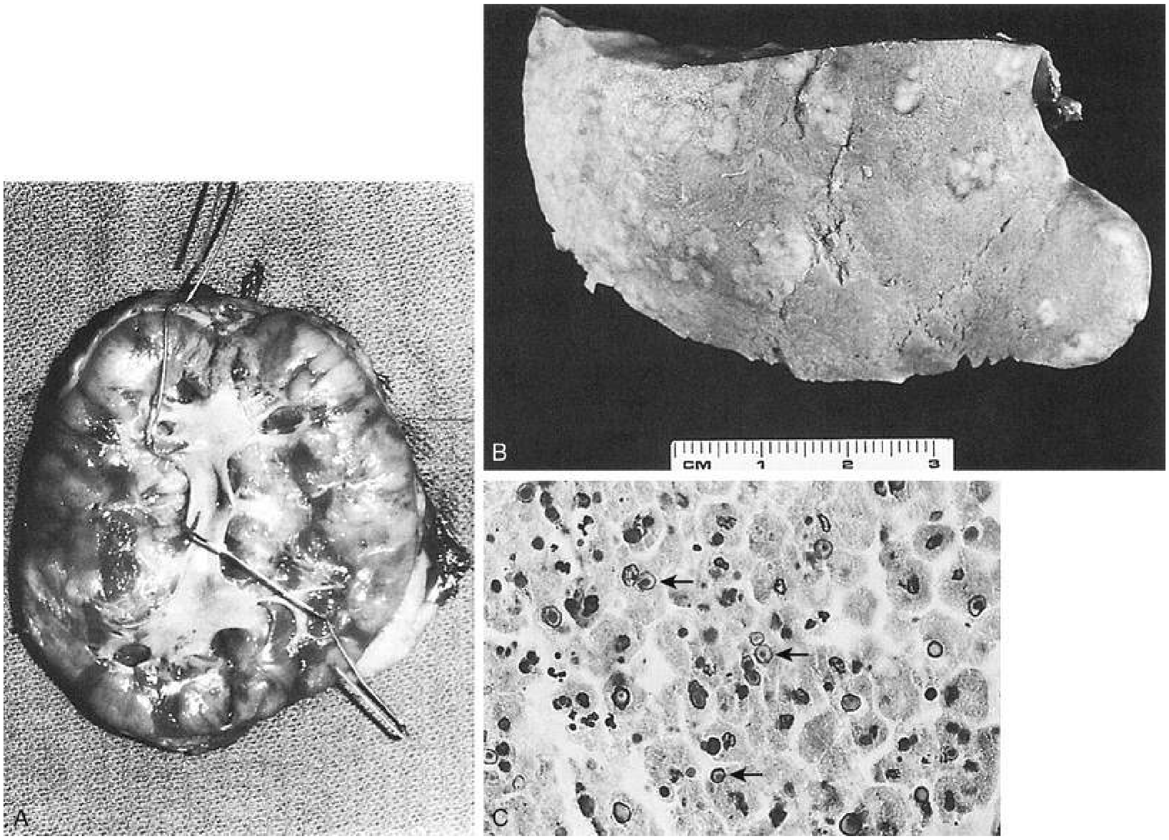

FIG. 55.39 Renal parenchymal malacoplakia. (A) Cut surface demonstrates extensive cortical and upper medullary replacement by multifocal, confluent, tumorlike masses. (B) Cortical surface exhibits multiple, firm, plaquelike lesions. (C) Hallmark of malacoplakia is demonstration of the Michaelis-Gutmann body *(arrows),* which represents incompletely destroyed bacteria surrounded by lipoprotein membrane (hematoxylin and eosin stain). (From Hartman DS: Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney: I and II. *Monogr Urol* 6:3, 1985.)

It has been shown that macrophages in malacoplakia involving the kidney and bladder contain large amounts of immunoreactive α_1-antitrypsin (Callea et al., 1982). The amount of α_1-antitrypsin remains unchanged during the morphogenetic stages of the pathologic process. Macrophages from other pathologic processes, closely resembling malacoplakia but without Michaelis-Gutmann bodies, do not contain α_1-antitrypsin except for a few macrophages in tuberculosis and XGP. **Therefore immunohistochemical staining for α_1-antitrypsin may be a useful test for an early and accurate differential diagnosis of malacoplakia.**

Clinical Presentation.

Most patients are older than 50 years. **The ratio of females to males with malacoplakia within the urinary tract is 4:1, but this disparity does not occur in other body tissues** (Stanton and Maxted, 1981). **The patients often are debilitated and immunosuppressed and have other chronic diseases. In fact, malakoplakia is increasingly described after solid organ transplantation, particularly renal transplant recipients** (Nieto-Rios et al., 2017). The symptoms of bladder malacoplakia are bladder irritability and hematuria. Cystoscopy reveals mucosal plaques or nodules. As these lesions progress, they may become fungating, firm, sessile masses that cause filling defects of the bladder, ureter, or pelvis on excretory urograms. The distal ureter may become strictured or stenotic and cause subsequent renal obstruction or nonfunction (Sexton et al., 1982). A typical patient with renal parenchymal disease may have one or more radiographic masses and chronic *E. coli* infections. Renal parenchymal malacoplakia may be complicated by renal vein thrombosis and inferior vena cava thrombosis (McClure, 1983). When malacoplakia involves the testis, epididymo-orchitis is present. Malacoplakia of the prostate is rare, but, when it occurs, it may be confused with carcinoma clinically (Shimizu et al., 2005). Mortality can exceed 50%, and the morbidity can be substantial (Stanton and Maxted, 1981).

Radiologic Findings.

Multifocal malacoplakia on excretory urography typically is seen as enlarged kidneys with multiple filling defects. Renal calcification, lithiasis, and hydronephrosis are absent. The multifocal nature is best appreciated by using ultrasonography, CT, or arteriography. Ultrasound examination may demonstrate renal enlargement and distortion of the central echo complex. The masses are often confluent, resulting in an overall increase in the echogenicity of the renal parenchyma (Hartman et al., 1980). On CT, the foci of malacoplakia are less dense than the surrounding enhanced parenchyma (Hartman, 1985). Arteriography typically reveals a hypovascular mass without peripheral neovascularity (Cavins and Goldstein, 1977; Trillo et al., 1977).

Unifocal malacoplakia on excretory urography appears as a noncalcified mass that is indistinguishable from other inflammatory or neoplastic lesions. Ultrasonography and CT may demonstrate a solid or cystic structure, depending on the degree of internal necrosis. Angiography may demonstrate neovascularity (Trillo et al., 1977). Extension beyond the kidney, which can occur with either multifocal or uniform malacoplakia, is best demonstrated by

CT.

Differential Diagnosis.

The differential diagnosis includes renal cystic disease, neoplasia, and renal inflammatory disease (Hartman, 1985). **Malacoplakia should be considered when one or more renal masses are observed, particularly in female patients with recurrent UTIs with *E. coli*, altered immune response syndromes, or cystoscopic evidence of malacoplakia or filling defects in the collecting system** (Charboneau, 1980)**. Malacoplakia should also be suspected when these radiographic findings occur in a renal transplant patient who has persistent UTI despite appropriate antimicrobial therapy.** Cystic disease generally can be excluded by careful sonographic and CT evaluations. Renal involvement with metastatic disease or lymphomas usually occurs late in the course of the disease, which is well established. Multifocal renal cell carcinoma is most often seen in the context of von Hippel-Lindau disease with its other clinical manifestations. Patients with XGP usually have signs and symptoms of UTI. As with malacoplakia, the involved kidney is enlarged but renal calculi and obstruction are common. Multiple renal abscesses are often associated with hematogenous dissemination resulting from cardiac disease.

Management.

Management of malacoplakia should be directed at control of the UTIs, which should stabilize the disease process. This subject is well reviewed by Stanton and Maxted (1981). Although multiple long-term antimicrobial agents, including many antituberculosis agents, have been used, the sulfonamides, rifampin, doxycycline, and TMP are thought to be especially useful because of their intracellular bactericidal activity (Maderazo et al., 1979). Fluoroquinolones are taken up by macrophages directly and have also proven effective in the management of malacoplakia (Vallorosi et al., 1999). Other investigators have used ascorbic acid and cholinergic agents such as bethanechol in conjunction with antimicrobial therapy and have reported good results (Abdou et al., 1977; Stanton et al., 1983; Zornow et al., 1979). Both agents are thought to increase intracellular cyclic guanosine monophosphate levels, which have been postulated as the biologic defect causing macrophage dysfunction. Surgical intervention, however, may be necessary if the disease progresses in spite of antimicrobial treatment. Nephrectomy is usually performed for the treatment of symptomatic unilateral renal lesions.

The long-term prognosis appears to be related to the extent of the disease. When parenchymal renal malacoplakia is bilateral or occurs in the transplanted kidney, death usually occurs within 6 months (Bowers and Cathey, 1971; Deridder et al., 1977). Patients with unilateral disease usually have a long-term survival after nephrectomy.

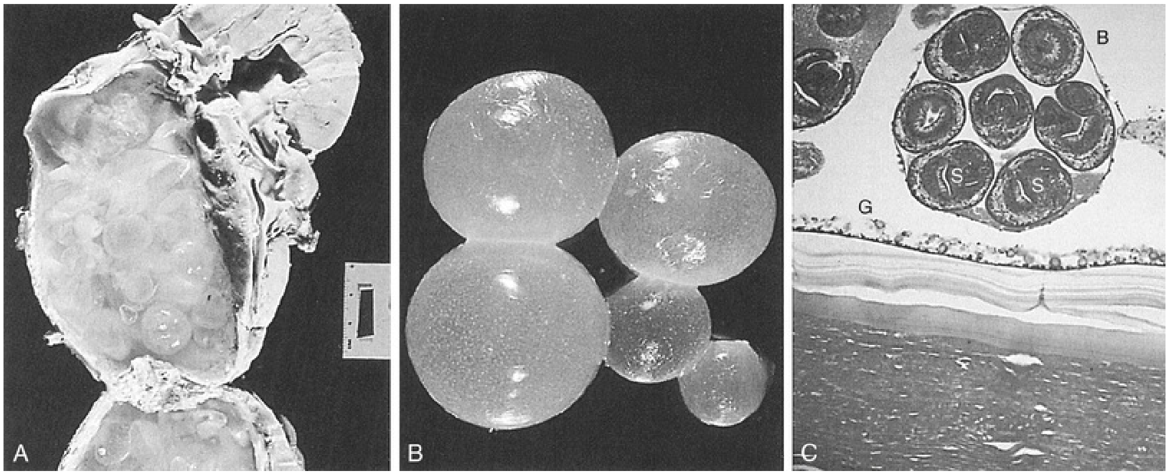
Renal Echinococcosis

Echinococcosis is a parasitic infection caused by the larval stage of the tapeworm *Echinococcus granulosus.* The disease is prevalent in dogs, sheep, cattle, and humans in South Africa, Australia, New Zealand, Mediterranean countries (especially Greece), and some parts of the former Soviet Union. In the United States, the disease is rare, but it is found in immigrants from Eastern Europe or other foreign endemic areas or as an indigenous infection among American Indians in the Southwest and in Eskimos (Plorde, 1977).

Pathogenesis and Pathology.

Echinococcosis is produced by the larval form of the tapeworm, which in its adult form resides in the intestine of the dog, the definitive host. The adult worm is 3 to 9 mm long. The ova in the feces of the dog contaminate grass and farmlands and are ingested by sheep, pigs, or humans, the intermediate hosts. Larvae hatch, penetrate venules in the wall of the duodenum, and are carried by the bloodstream to the liver. Those larvae that escape the liver are next filtered by the lungs. Approximately 3% of the organisms that escape entrapment in the liver and lungs may then enter the systemic circulation and infect the kidneys. The larvae undergo vesiculation, and the resultant hydatid cyst gradually develops at a rate of about 1 cm/yr. Thus the cyst may take 5 to 10 years to reach pathologic size.

Echinococcosis cysts of the kidney are usually single and located in the cortex (Nabizadeh et al., 1983). The wall of the hydatid cyst has three zones: a peripheral zone of fibroblasts derived from tissues of the host becomes the adventitia and may calcify; an intermediate laminated layer becomes hyalinized; and a single inner layer is composed of nucleated epithelium and is called the *germinal layer.* The germinal layer gives rise to brood capsules that increase in number, become vacuolated, and remain attached to the germinal membrane by a pedicle. New larvae (scoleces) develop in large numbers from the germinal layer within the brood capsule (eFig. 55.40). The hydatid cyst is also filled with fluid. When brood capsules detach, they enlarge and move freely in the fluid and are then called daughter cysts. Hydatid sand is composed of free larvae and daughter cysts.



EFIG. 55.40 Echinococcosis. (A) Gross specimen. A cystic mass measuring 7 × 11 cm in lower pole. Smaller daughter cysts are identified within the larger cystic mass. (B) Gross specimen. Daughter cysts represent brood capsules that have detached and move freely. (C) Photomicrograph. Brood capsules *(B)* arising from the germinal layer *(G)* contain viable and degenerating scoleces *(S).* (From Hartman DS: Radiologic pathologic correlation of the infectious granulomatous diseases of the kidney: III and IV. *Monogr Urol* 6:26, 1985.)

Clinical Presentation.

The symptoms of echinococcosis are those of a slow-growing tumor. Most patients are asymptomatic or have a flank mass, dull pain, or hematuria (Gilsanz et al., 1980; Nabizadeh et al., 1983). Because the cyst is focal, it rarely affects renal function. Rarely, the cyst ruptures into the collecting system, and the patient may experience severe colic and passage of debris resembling grape skins in the urine (hydatiduria). The cyst may also rupture into an adjacent viscus or the peritoneal cavity. The fluid is extremely antigenic (Hartman, 1985).

Laboratory Diagnosis.

If cyst rupture occurs, the definitive diagnosis can be established by identifying daughter cysts in the urine or by identifying the laminated wall of the cyst (Sparks et al., 1976). Fewer than half of the patients have eosinophilia. The most reliable diagnostic test uses partially purified hydatid arc 5 antigens in a double-diffusion test (Coltorti and Varela-Diaz, 1978).

Complement fixation, hemagglutination, and the Casoni intradermal skin tests are less reliable but, when combined, are positive in about 90% of patients (Sparks et al., 1976).

Radiologic Findings.

Excretory urography typically shows a thick-walled cystic mass, occasionally calcified (Buckley et al., 1985). If the cyst ruptures into the collecting system, daughter cysts may be outlined in the pelvis as an irregular mass or as multiple solitary lesions (Gilsanz et al., 1980). Occasionally, direct filling of the cyst with contrast medium occurs.

Ultrasonography and CT are useful in characterizing the mass. Ultrasonography usually demonstrates a multicystic or multiloculated mass. A sudden change in position may demonstrate bright falling echoes corresponding to hydatid sand, which can be observed during real-time evaluation of hydatid cysts (Saint Martin, 1984).

On CT, several patterns of renal echinococcosis may be recognized. The most specific is a cystic mass with discrete, round daughter cysts and a well-defined enhancing membrane (Martorana et al., 1981). The less specific pattern is that of a thick-walled multiloculated cystic mass (Gilsanz et al., 1980). The presence of daughter cysts within the mother cyst differentiates the lesion from a simple renal cyst and from renal abscesses, infected cysts, and necrotic neoplasm.

CT and ultrasonography are useful in evaluating the liver. Angiography is seldom required. **Diagnostic aspiration should not be performed because of the danger of rupture and spillage of the highly antigenic cyst contents and risk of fatal anaphylaxis.** Nevertheless, Baijal et al. (1995) described a percutaneous management of renal hydatidosis as a minimally invasive diagnostic and therapeutic option.

Management.

The prognosis of echinococcosis is good but depends on the site and size of the cysts. Medical treatment with benzimidazole compounds such as mebendazole or albendazole has shown limited success with significant side effects (Nabizadeh et al., 1983).

Surgery remains the mainstay of treatment of renal echinococcosis (Poulios, 1991)**. The cyst should be removed without rupture to reduce the chance of seeding, antigen reaction, and recurrence.** If the cyst wall is calcified, the larvae are probably dead and the risk of seeding is low, although a daughter cyst may be viable. **If the cyst ruptures or cannot be removed and marsupialization is required, the contents of the cyst initially should be aspirated and filled with a scolicidal agent** such as 30% sodium chloride, 0.5% silver nitrate, 2% formalin, or 1% iodine for approximately 5 minutes to kill the germinal portion (Nabizadeh et al., 1983; Shetty et al., 1992; Sparks et al., 1976).

Key Points: Kidney Infections

- Acute pyelonephritis classically is seen as the abrupt onset of chills, fever, and flank or costovertebral angle tenderness but can involve symptoms as mild as cystitis or as severe as sepsis.
- Emphysematous pyelonephritis is a life-threatening infection diagnosed radiographically by the presence of gas in the parenchyma or collecting system and can be managed via percutaneous drainage or surgically.
- Renal abscesses are well delineated by CT and are classically managed with IV antimicrobial agents and drainage. Smaller abscesses may be amenable to conservative treatment with medical management.
- Pyonephrosis is a bacterial infection in a hydronephrotic kidney. Prompt diagnosis is critical; treatment entails intravenous antimicrobial agents and drainage of the obstructed renal unit.
- XGP is a chronic renal infection that is often found in poorly functioning renal units obstructed secondary to nephrolithiasis. XGP can be mistaken for renal tumors.
- Malacoplakia is an unusual inflammatory disease thought to result from abnormal macrophage function. Michaelis-Gutmann bodies are lysosomal inclusion bodies that characterize this disease microscopically.

Other Infections

Fournier Gangrene

Fournier gangrene is a potentially life-threatening form of necrotizing fasciitis involving the male genitalia. It is also known as idiopathic gangrene of the scrotum, streptococcal scrotal gangrene, perineal phlegmon, and spontaneous fulminant gangrene of the scrotum (Fournier, 1883, 1884). As originally reported by Baurienne in 1764, then by Fournier in 1883, it was characterized by an abrupt onset of a rapidly fulminating genital gangrene of idiopathic origin in previously healthy young patients that resulted in gangrenous destruction of the genitalia. The disease now differs from these descriptions in that it involves a broader age range, including older patients (Bejanga, 1979; Wolach et al., 1989), follows a more indolent course, and has a less abrupt onset; and, in approximately 95% of the cases, a source can now be identified (Burpee and Edwards, 1972; Jamieson et al., 1984; Kearney and Carling, 1983; Macrea, 1945; Spirnak et al., 1984).

Infection most commonly arises from the skin, urethra, or rectal regions. An association between urethral obstruction associated with strictures and extravasation and instrumentation has been well documented. **Predisposing factors include diabetes mellitus, local trauma, paraphimosis, periurethral extravasation of urine, perirectal or perianal infections, and surgery such as circumcision or herniorrhaphy. In cases originating in the genitalia, specifically as a result of urethral obstruction, the infecting bacteria probably pass through Buck fascia of the penis and spread along the Dartos fascia of the scrotum and penis, Colles fascia of the perineum, and Scarpa fascia of the anterior abdominal wall.** In view of the typical foul odor associated with this condition, a major role for anaerobic bacteria is likely. **Wound cultures generally yield multiple organisms, implicating anaerobic-aerobic synergy** (Cohen, 1986; Meleney, 1933; Miller, 1983). Mixed cultures containing facultative organisms (*E. coli*, *Klebsiella*, enterococci) along with anaerobes (*Bacteroides*, *Fusobacterium*, *Clostridium*, microaerophilic streptococci) have been obtained from the lesions.

Clinical Presentation

Patients frequently have a history of recent perineal trauma,

instrumentation, urethral stricture associated with sexually transmitted disease, or urethral cutaneous fistula. Pain, rectal bleeding, and a history of anal fissures suggest a rectal source of infection. Dermal sources are suggested by history of acute and chronic infections of the scrotum and spreading recurrent hidradenitis suppurativa or balanitis.

The infection commonly starts as cellulitis adjacent to the portal of entry. Early on, the involved area is swollen, erythematous, and tender as the infection begins to involve the deep fascia. Pain is prominent, and fever and systemic toxicity are marked (Paty and Smith, 1992). The swelling and crepitus of the scrotum quickly increase, and dark purple areas develop and progress to extensive gangrene. If the abdominal wall becomes involved in an obese patient with diabetes, the process can spread very rapidly. Specific GU symptoms associated with the condition include dysuria, urethral discharge, and obstructed voiding. Alterations in mental status, tachypnea, tachycardia, and temperature greater than 38.3°C (101°F) or less than 35.6°C (96°F) suggest gram-negative sepsis.

Laboratory Diagnosis and Radiologic Findings

Anemia occurs secondary to a decreased functioning erythrocyte mass caused by thrombosis and ecchymosis coupled with decreased production secondary to sepsis (Miller, 1983). Elevated serum creatinine levels, hyponatremia, and hypocalcemia are common. Hypocalcemia is believed to be secondary to bacterial lipases that destroy triglycerides and release free fatty acids that chelate calcium in its ionized form.

Because crepitus (subcutaneous gas) is often an early finding, a plain film of the abdomen may be helpful in identifying air. Scrotal ultrasonography is also useful in this regard. Biopsy of the base of an ulcer is characterized by superficially intact epidermis, dermal necrosis, vascular thrombosis, and polymorphonuclear leukocyte invasion with subcutaneous tissue necrosis. Stamenkovic and Lew (1984) noted that the use of frozen sections within 21 hours after the onset of symptoms could confirm a diagnosis earlier and lead to early institution of appropriate treatment.

Management

Prompt diagnosis is critical because of the rapidity with which the process can progress. The clinical differentiation of necrotizing fasciitis from cellulitis may be difficult because the initial signs including pain, edema, and erythema are not distinctive. However, **the presence of marked systemic toxicity out of proportion to the local finding should alert the clinician.** Intravenous hydration and antimicrobial therapy are indicated in preparation for surgical debridement. Antimicrobial regimens include broad-spectrum antibiotics (β-lactam plus β-lactamase inhibitor) such as piperacillin-tazobactam (especially if *Pseudomonas* is suspected), ampicillin plus sulbactam, or vancomycin or carbapenems plus clindamycin or metronidazole (Morpurgo and Galandiuk, 2002).

Immediate debridement is essential. In the patient in whom diagnosis is clearly suspected on clinical grounds (deep pain with patchy areas of surface hypoesthesia or crepitation, or bullae and skin necrosis), direct operative intervention is indicated. **Extensive incision should be made through the skin and subcutaneous tissues, going beyond the areas of involvement until normal fascia is found. Necrotic fat and fascia should be excised, and the wound should be left open. A second procedure 24 to 48 hours later is indicated if there is any question about the adequacy of initial debridement**. **Orchiectomy is almost never required** because the testes have their own blood supply independent of the compromised fascial and cutaneous circulation to the scrotum. **Suprapubic diversion should be performed in cases in which urethral trauma or extravasation is suspected. Colostomy should be performed if there is colonic or rectal perforation.** Hyperbaric oxygen therapy has shown some promise in shortening hospital stays, increasing wound healing, and decreasing the gangrenous spread when used in conjunction with debridement and antimicrobials (Paty and Smith, 1992). Once wound healing is complete, reconstruction (e.g., using myocutaneous flaps) improves cosmetic results.

Outcome

The mortality rate averages approximately 20% (Baskin et al., 1990; Clayton et al., 1990; Cohen, 1986) but ranges from 7% to 75%. Higher mortality rates are found in patients with diabetes, alcoholics, and those with colorectal sources of infection who often have a less typical presentation, greater delay in diagnosis, and more widespread extension. Regardless of the presentation, **Fournier gangrene is a true urologic emergency that demands early recognition, aggressive treatment with antimicrobial agents, and surgical debridement to reduce morbidity and mortality.**

Periurethral Abscess

Periurethral abscess is a life-threatening infection of the male urethra and periurethral tissues. Initially, the area of involvement can be small and localized by Buck fascia. However, when Buck fascia is penetrated, there can be extensive necrosis of the subcutaneous tissue and fascia. Fasciitis can spread as far as the buttocks posteriorly and the clavicle superiorly. Rapid diagnosis and treatment are essential to reduce the morbidity and high mortality historically associated with this disease.

Pathogenesis

Periurethral abscess is frequently a sequela of gonorrhea, urethral stricture disease, or urethral catheterization. Frequent instrumentation is also associated with periurethral abscess formation. The source of the infecting organism is the urine. Gram-negative rods, enterococci, and anaerobes are most frequently identified. The presence of multiple organisms is common. Anaerobes, normal residents of the male urethra, are also frequently found in wound cultures.

Clinical Presentation

Presenting signs and symptoms include scrotal swelling in 94% of patients, fever (70%), acute urinary retention (19%), spontaneously drained abscess (11%), and dysuria or urethral discharge (5% to 8%). The average interval between initial symptoms and presentation is 21 days. Urinalysis of the first glass specimen reveals pyuria and bacteriuria.

Management

Treatment consists of immediate suprapubic urinary drainage and wide debridement. Antimicrobial therapy with an aminoglycoside and a cephalosporin is usually adequate for empirical coverage. More selective antimicrobial therapy can be instituted when the antimicrobial susceptibility of the organisms is available. Perineal urethrostomy or chronic suprapubic diversion occasionally has been helpful to prevent recurrences, and it should be considered in patients with diffuse stricture disease. The presence of a malignancy is unusual, but biopsy is important.

Key Points: Other Infections

- Fournier gangrene is necrotizing fasciitis arising from the perineal skin, scrotum, urethra, or rectum.
- Emergent surgical debridement and broad-spectrum antimicrobial agents are the essentials of treatment of Fournier gangrene.
- Periurethral abscess can occur secondarily to urethral stricture or catheterization; treatment entails surgical debridement, suprapubic urinary drainage, and antimicrobial agents.

Bacteremia, Sepsis, and Septic Shock

Sepsis is a clinical syndrome characterized by extremes of body temperature, heart rate, respiratory rate, and WBC count that occurs in response to an infection. A detailed list of potential characteristics can be found in Box 55.12. Severe sepsis and septic shock are extensions of the sepsis spectrum and involve acute organ dysfunction and life-threatening hypotension not responsive to fluid resuscitation (Dellinger et al., 2008). A typical host response to infection involves localized containment and elimination of bacteria and repair of damaged tissue. This process is facilitated by macrophages and dendritic cells and orchestrated by $CD4^+$ T helper cells via the release of proinflammatory and anti-inflammatory molecules (cytokines, chemokines, interferons). Sepsis occurs when a local infectious process becomes an uncontrolled systemic blood-borne inflammatory response resulting in damage to tissues or organs remote from the initial site of infection or injury. The extremes of the spectrum are lethal in one in four patients, and there are an estimated 750,000 cases (3 cases per 1000 population) of sepsis or septic shock in the United States each year (Dellinger et al., 2008; Rivers et al., 2001). Much like other medical emergencies, including polytrauma, acute myocardial infarction, and stroke, early recognition and appropriate treatment significantly influence outcome; these are commonly known as "the golden hours."

Box 55.12

Potential Characteristics of Sepsis Spectrum

General

Fever (core temperature >38.3°C)
Hypothermia (core temperature <36°C)
Heart rate >90 min, 1 or 2 SD above the normal value for age
Tachypnea
Altered mental status
Significant edema or positive fluid balance (20 mL/kg/24 h)
Hyperglycemia (plasma glucose >120 mg/dL or 7.7 mmol/L) in the

absence of diabetes

Inflammatory

Leukocytosis (WBC count >12,000/µL)
Leukopenia (WBC count <4000/µL)
Normal WBC count with >10% immature forms

Organ Dysfunction

Arterial hypoxemia ($\mathrm{PaO_2/FIO_2} > 300$)
Acute oliguria (urine output 0.5 mL/kg in 1 h for at least 2 h)
Creatinine increase of 0.5 mg/dL
Coagulation abnormalities (INR 1.5 or aPTT >60 sec)
Ileus (absent bowel sounds)
Thrombocytopenia (platelet count <100,000/µL)
Hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 mmol/L)

Tissue Perfusion

Hyperlactatemia (>1 mmol/L)
Decreased capillary refill or mottling

aPTT, Activated partial thromboplastin time; *INR,* international normalized ratio; *SD,* standard deviation; *WBC,* white blood cell.

Data from Levy MM, Fink MP, Marshall JC, et al.: 2001 SCCM/ESICM/ACCP/ATS/SIS International Sepsis Definitions Conference. *Crit Care Med* 31:1250–1256, 2003.

Definitions

- **Bacteremia:** the presence of viable bacteria in the blood
- **Systemic inflammatory response syndrome (SIRS):** a clinical syndrome characterized by the 2001 International Sepsis Definitions Conference (Levy et al., 2003) as extremes of body

temperature, heart rate, ventilation, and immune response. **SIRS can occur in response to multiple insults, including systemic infection, trauma, thermal injury, or a sterile inflammation.**

- **Sepsis:** SIRS and infection either documented or strongly suspected
- **Severe sepsis: sepsis plus sepsis-induced organ dysfunction or tissue hypoperfusion, typically systolic blood pressure (SBP) less than 90 mm Hg or mean arterial pressure (MAP) less than 70 mm Hg**
- **Septic shock:** an extreme form of sepsis with sepsis-induced hypotension persisting despite adequate fluid resuscitation; findings may include elevated lactic acid or oliguria

Pathophysiology

Initial studies of pathophysiologic features of septic shock concentrated on the interactions of lipopolysaccharides (LPS) from the gram-negative bacterial cell wall with various innate immune system pathways. More recent investigations now focus on understanding the activation and regulation of the innate and acquired immune systems and the array of cytokines that are released during localized and systemic inflammatory responses.

Bacterial Cell Wall Components in Septic Shock

The exotoxins produced by some bacteria (e.g., exotoxin A produced by *P. aeruginosa*) can initiate septic shock. **However, the bacteria themselves, and in particular their cell wall components, are primarily responsible for the development of septic shock. These components activate numerous innate immunologic pathways, including macrophages, neutrophils, and dendritic cells and the complement system. The prime initiator of gram-negative bacterial septic shock is endotoxin, an LPS component of the bacterial outer membrane.** Endotoxin can directly activate the coagulation, complement, and fibrinolytic systems, leading to the release of small molecules that cause vasodilation and increased endothelial permeability (Tapper and Herwald, 2000).

Cytokine Network

Monocytic cells appear to have a pivotal role in mediation of the biologic effects of SIRS and septic shock. Monocytes can remove and detoxify LPS and be beneficial to the host. However, LPS-stimulated monocytes produce cytokines such as tumor necrosis factor (TNF) and interleukin (IL)-1. The intravascular activation of inflammatory systems involved in septic shock is mainly the consequence of an overproduction of these and other cytokines. Production of these cytokines is modulated by $CD4^+$ T helper cells. Type I $CD4^+$ T helper cells release proinflammatory cytokines including TNF-α, interferon-γ, and IL-2. These cytokines are also produced by macrophages, endothelial cells, and other cells stimulated by microbial products. The systemic release of large amounts of the cytokine TNF is associated with death from septic shock in humans (Calandra et al., 1988; Girardin et al., 1988; Waage, 1987). However, despite the fact that TNF is classically regarded as a central mediator of pathophysiologic changes associated with sepsis, the role of attenuation of this and other proinflammatory cytokines remains unclear. For example, in one animal model of peritonitis, survival was worsened by the administration of antibodies blocking TNF (Eskandari et al., 1992). Also, patients suffering from rheumatoid arthritis treated with TNF-α agents remain susceptible to the development of septic shock. Last, a meta-analysis of clinical trials using anti-inflammatory agents in sepsis suggested these agents were generally harmful in all but a small subset of patients (Hotchkiss and Karl, 2003). More recently, anti-inflammatory cytokines, including IL-4 and IL-10, released by type II $CD4^+$ T helper cells, have also been noted to be elevated in sepsis, further illustrating the complex regulation of proinflammatory and anti-inflammatory cytokines in a septic patient. In summary, proinflammatory and anti-inflammatory cytokines are elements of early sepsis; however, the role of cytokine modulation in the treatment of sepsis remains unclear.

Clinical Presentation and Diagnosis

Early signs of systemic inflammatory response syndrome include temperature extremes (>38°C [100.4°F] or <36°C [96.8°F]), tachycardia (heart rate >90 beats/min), tachypnea, and altered mental status. The classic bedside findings differentiating septic shock from other types of shock include a warm patient, brisk capillary refill, and a bounding pulse reflecting pyrexia, peripheral vasodilation, and decreased systemic vascular resistance. Other diagnostic criteria include evidence of organ dysfunction

such as hypotension, oliguria, or ileus and **laboratory abnormalities** including leukocytosis or leukopenia, hyperbilirubinemia, hyperlactatemia, hyperglycemia, coagulation abnormalities, and elevated C-reactive protein and procalcitonin (see Box 55.12). The classic clinical presentation of fever and chills followed by hypotension is manifest only in about 30% of patients with gram-negative bacteremia (McClure, 1983). Even before temperature extremes and the onset of chills, bacteremic patients often begin to hyperventilate. Thus the **earliest metabolic change in septicemia is a resultant respiratory alkalosis.** In critically ill patients, the sudden onset of hyperventilation should lead to blood drawing for culture and careful evaluation of the patient. **Changes in mental status can also be important clinical clues.** Although the most common pattern is lethargy or obtundation, an occasional patient may become excited, agitated, or combative. Cutaneous manifestations such as the bull's-eye lesion associated with *P. aeruginosa* may be identified.

Metastatic infections secondary to GU tract bacteremia have been described (Siroky et al., 1976). In this review of 137 patients who developed metastatic infections from bacteremia with a GU source, 79% had undergone prior urologic instrumentation, 59% developed skeletal infections, mainly of the spine, and 29% developed endocarditis, most commonly caused by *E. faecalis*.

Bacteriology

In classic studies of sepsis syndrome and septic shock, gram-negative bacteria were predominant organisms isolated in 30% to 80% of cases and gram-positive bacteria in 5% to 24% (Bone, 1991; Calandra et al., 1988; Ispahani et al., 1987). Although *E. coli* is the most common organism causing gram-negative bacteremia, many nosocomial catheter-associated infections are caused by highly resistant gram-negative organisms: *P. aeruginosa*, *Proteus*, *Providencia*, and *Serratia* spp. *Acinetobacter* and *Enterobacter* spp. are also emerging as important nosocomial pathogens. In a large series, *E. coli* caused about one-third of the cases; the *Klebsiella-Enterobacter-Serratia* family, approximately 20%; and *Pseudomonas*, *Proteus*, *Providencia*, and anaerobic species, approximately 10% each (Kreger et al., 1980). Anaerobic organisms may cause bacteremia when the source is a postsurgical intra-abdominal abscess or transrectal prostatic biopsy. **More recent studies suggest the incidence of sepsis caused by gram-positive bacterial and fungal organisms is increasing** (Martin et al., 2003) **and reinforce the need for initial broad-spectrum**

antimicrobial coverage.

Management

The principles of management of sepsis include resuscitation, supportive care, monitoring, administration of broad-spectrum antimicrobial agents, and drainage or elimination of infection (Dellinger et al., 2008; Sessler et al., 2004). Although the identification and early intervention of sepsis by the urologist is important, the use of expert consultants is also recommended because management of sepsis and the critically ill patient is complex and always evolving. Early goal-directed therapy remains the standard approach since it was shown to be significantly beneficial in a 263-patient study by Rivers et al. (2001).

Principles of resuscitation include support of the airway and breathing and optimization of perfusion with the use of invasive pressure monitoring with central access (Rivers et al., 2001). Intubation and mechanical ventilation may be required in patients who are obtunded and unable to protect their airway. Supplemental oxygen may be instituted, but supranormal oxygen delivery is no longer considered a goal of therapy (Dellinger et al., 2008). **Tissue perfusion should first be optimized** with fluid resuscitation to restore mean circulating filling pressures; this may include crystalloid and or colloid/blood products. If additional blood pressure support is needed, vasoactive agents including phenylephrine, norepinephrine, vasopressin, and dopamine can be instituted; however, low-dose dopamine administration for renal protection is no longer recommended by critical care experts. Other principles of resuscitation and supportive care include optimization of oxygen delivery, correction of coagulopathies if clinically significant, maintenance of blood glucose levels below 110 mg/dL with intensive insulin therapy (van den Berghe et al., 2001), and implementation of hemofiltration as needed (Schiffl et al., 2002). The use of hydrocortisone therapy in septic shock patients did not show a survival or disease-specific benefit in patients in a large study (Sprung et al., 2008).

Identification of the presumptive source of infection and cultures from corresponding fluids and blood should be obtained before the initiation of antimicrobial therapy. Multiple blood cultures for aerobic and anaerobic organisms should be obtained. In addition, all potential sources of bacteremia must be cultured (i.e., urine, sputum, and wounds). Careful attempts to identify the source of infection should be made because the choice of appropriate antimicrobial coverage depends on the organisms that are thought most likely to cause the infection. The severity of the underlying disease and the possibility of synergistic interactions are also important considerations. **If the urinary tract is the most likely portal of entry, a broad-spectrum antimicrobial either alone or in combination with an aminoglycoside should be administered. Three clinical factors have been predictive of the subsequent isolation of a resistant pathogen: (1) the use of an antimicrobial drug in the last month, (2) advanced age, and (3) male sex** (Leibovici et al., 1992). If the infection is hospital acquired, or if the patient has had multiple infections or is immunocompromised or severely ill, an aminoglycoside and anti-*Pseudomonas* β-lactam or a third-generation cephalosporin should be used. When identification and drug susceptibilities of the offending organism are known, antimicrobial therapy should be changed to use the lowest cost, least toxic antimicrobial with the narrowest antimicrobial coverage. Antimicrobial treatment should be continued until the patient has been afebrile for 3 to 4 days and is clinically stable. Local infections that may have provided the focus for the bacteremia should be treated individually as appropriate. The surviving sepsis campaign suggests the initiation of broad-spectrum antibiotics within 1 hour of diagnosis of septic shock (Dellinger et al., 2008).

Key Points: Bacteremia, Sepsis, and Septic Shock

- Sepsis is a clinical syndrome characterized by extremes of body temperature, heart rate, respiratory rate, and WBC count that occurs in response to an infection.
- The principles of management of sepsis include resuscitation, supportive care, monitoring, administration of broad-spectrum antimicrobial agents, and drainage or elimination of infection.
- The surviving sepsis campaign and early goal-directed therapy have been shown to improve outcomes in critically ill patients.

Bacteriuria in Pregnancy

Pregnancy

The prevalence of bacteriuria in pregnant women varies from 4% to 7%,

and the incidence of acute clinical pyelonephritis ranges from 25% to 35% in untreated bacteriuric women (Stamey, 1980). This is probably the result of dilation of the ureters and pelvis of the kidney secondary to pregnancy-related hormonal alterations. In addition, urine obtained from a pregnant woman at any gestational stage exhibits a more suitable pH for growth of *E. coli* (Asscher et al., 1973). **It is not surprising that untreated bacteriuria in the first trimester is accompanied by a substantial increase in the incidence of acute pyelonephritis because half of these women have upper tract bacteriuria** (Fairley et al., 1966).

Untreated bacteriuria involving these dilated upper tracts could be expected to cause a significant number of abnormalities that should be radiologically apparent. Kincaid-Smith and Bullen (1965) performed a culture on 4000 women at their first antenatal visit. Out of 240 bacteriuric women, 148 returned for excretory urography 6 weeks after delivery. Approximately 40% of these patients had radiologic abnormalities consistent with pyelonephritis or analgesic nephritis. Brumfitt et al. (1967) showed that the incidence of radiologic abnormalities in bacteriuria of pregnancy was proportional to the difficulty in clearing the infection. Patients who responded promptly to a single course of therapy had a 23% incidence of radiologic abnormalities, but those who remained bacteriuric despite repeated therapeutic efforts had a 65% incidence of radiologic changes. Thus prolonged bacteriuria and pyelonephritis of pregnancy appear to be **associated** with significant radiologic abnormalities. However, there is little evidence to suggest that bacteriuria of pregnancy or acute pyelonephritis of pregnancy **causes** these renal radiologic abnormalities.

Recurrent UTIs are common in pregnant women and can result in preterm labor and low-birth-weight babies. All pregnant women should routinely be screened for bacteriuria. Aggressive management of the bacteriuria is necessary: as stated earlier, pregnant women are one of the few categories of patients who require treatment of asymptomatic bacteriuria, per the IDSA guidelines. **Screening with urine culture is recommended at the initial visit by the American College of Obstetricians and Gynecologists (ACOG). Treatment of asymptomatic bacteriuria has been shown to reduce morbidity and complications. Asymptomatic bacteriuria is one of the most common infectious issues encountered during pregnancy. The prevalence of asymptomatic bacteriuria does not change with the occurrence of pregnancy and ranges from 2% to 7%** (Hooton et al., 2000). The risk of acquiring bacteriuria during pregnancy increases with lower socioeconomic class, multiparity, and sickle cell traits (Patterson and Andriole, 1987; Stenqvist et al., 1989).

The site of bacteriuria in pregnant female patients probably also reflects the situation before conception. In two studies that localized the origin of the bacteriuria, one using the Stamey ureteral catheterization technique and the other the Fairley bladder washout, upper tract infections were found in 44% and 24.5% of pregnant female patients, respectively (Fairley et al., 1966; Heineman and Lee, 1973). In non-pregnant females with recurrent bacteriuria, Stamey (1980) has reported about a 50% probability that the origin is in the upper tract. With other techniques, which may reflect the severity of tissue infection rather than the location of infection, the results are similar; approximately 50% of women with screening bacteriuria of pregnancy are fluorescent antibody-positive (Fa^+) and thus have evidence of upper tract infection (Harrison et al., 1974). Fairley and his group (1973) found that the site of infection is unrelated to the likelihood that pyelonephritis will develop during pregnancy.

Spontaneous resolution of bacteriuria detected by standard urine culture in pregnant women is unlikely unless it is treated. Non-pregnant patients often clear their asymptomatic bacteriuria (Hooton et al., 2000)**, but pregnant women become symptomatic more frequently and tend to remain bacteriuric** (Elder et al., 1971).

Pyelonephritis develops in 1% to 4% of all pregnant women (Sweet, 1977) **and in 15% to 45% of pregnant women with untreated bacteriuria** (Pedler and Bint, 1987; Wright et al., 1993). **Of the women who develop pyelonephritis during pregnancy, 60% to 75% acquire it during the third trimester** (Cunningham et al., 1973), **when hydronephrosis and stasis in the urinary tract are most pronounced. As many as 10% to 20% of pregnant women who get pyelonephritis develop it again before or just after delivery** (Cunningham et al., 1973; Gilstrap et al., 1981). Moreover, a third of pregnant women who develop pyelonephritis have a documented prior history of pyelonephritis (Gilstrap et al., 1981). **The increased likelihood that bacteriuria may progress to acute pyelonephritis during pregnancy alters the morbidity of bacteriuria for this group. Treatment of screening bacteriuria of pregnancy decreases the incidence of acute pyelonephritis during pregnancy from a range of 13.5% to 65% to a range of 0 to 5.3%** (Sweet, 1977).

Pathogenesis

The anatomic and physiologic changes induced by the gravid state significantly alter the natural history of bacteriuria (Patterson and Andriole, 1987). **These changes may cause pregnant women to be more susceptible to pyelonephritis and may require alteration of therapy.** These changes have been well summarized in several reviews (Davidson and Talner, 1978; Waltzer, 1981).

Anatomic and Physiologic Changes During Pregnancy

Increase in Renal Size

Renal length increases approximately 1 cm during normal pregnancy. It is thought that this does not represent true hypertrophy but is the result of increased renal vascular and interstitial volume. No histologic changes have been identified in renal biopsies (Waltzer, 1981).

Smooth Muscle Atony of the Collecting System and Bladder

The collecting system, especially the ureters, undergoes decreased peristalsis during pregnancy, and most women in their third trimester show significant ureteral dilation (Davison and Lindheimer, 1978; Kincaid-Smith, 1978; Waltzer, 1981; Fig. 55.41). **This hydroureter has been attributed to the muscle-relaxing effects of increased progesterone during pregnancy and to mechanical obstruction of the ureters by the enlarging uterus at the pelvic brim.** Progesterone-induced smooth muscle relaxation also may cause an increased bladder capacity (Waltzer, 1981). Later in pregnancy, the dilation may be the result of the obstructive effect of the enlarging uterus (Poole and Thorsen, 1999).

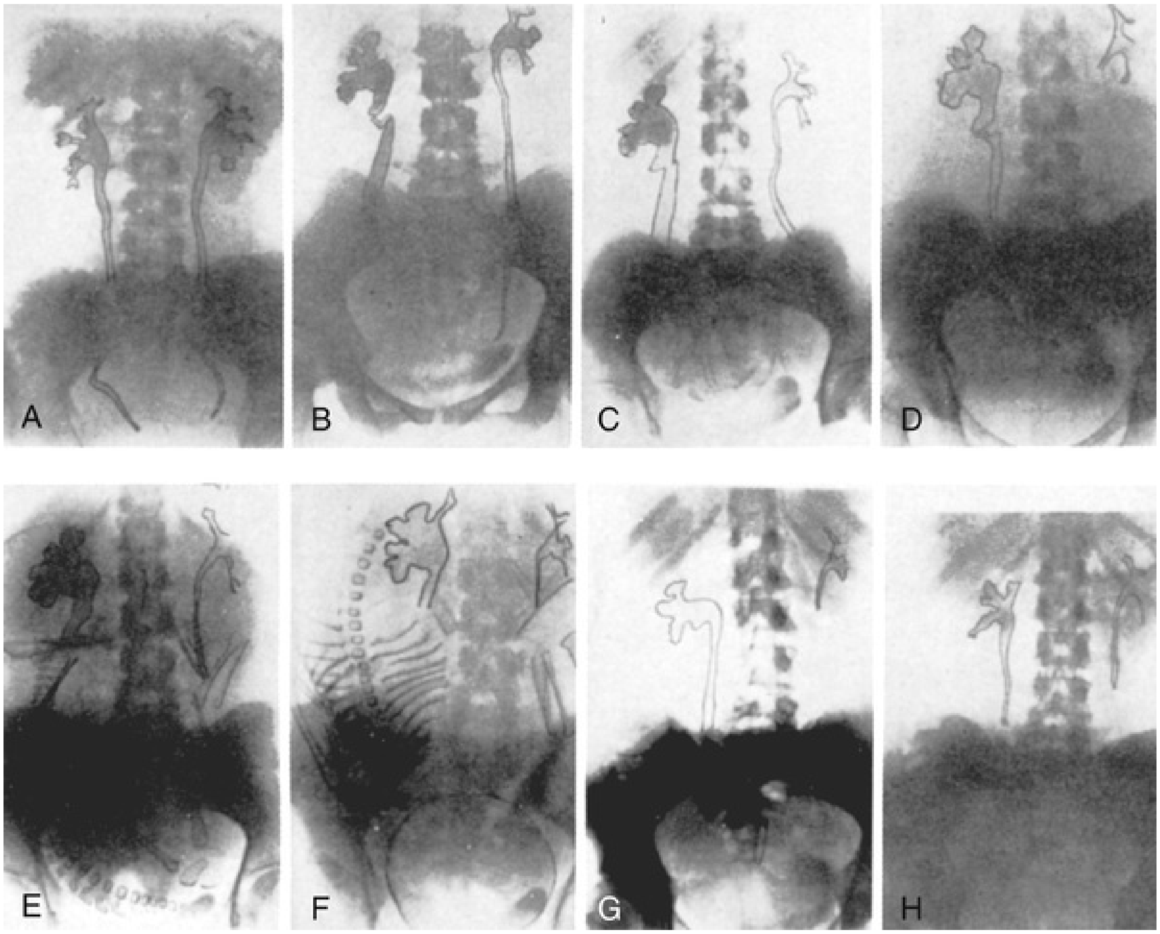


FIG. 55.41 Progressive hydroureter and hydronephrosis observed on intravenous pyelogram during a normal pregnancy. (A) 15 weeks; (B) 18 weeks; (C) 22 weeks; (D) 26 weeks; (E) 34 weeks; (F) 39 weeks; (G) 1 week postpartum; (H) 6 weeks postpartum. Bilateral hydroureter and hydronephrosis are shown as early as 15 weeks (A). (B to H) Successive urograms are from one patient during a normal pregnancy. Dilation occurs mainly on the right side, and both urinary tracts are normal by 6 weeks after delivery. (From Hundley JM, Walton HJ, Hibbits JT, et al.: Physiologic changes occurring in the urinary tract during pregnancy. *Am J Obstet Gynecol* 30:625–649, 1935.)

Bladder Changes

The enlarging uterus displaces the bladder superiorly and anteriorly. The bladder becomes hyperemic and may appear congested when viewed endoscopically (Waltzer, 1981). Estrogen stimulation probably causes bladder hypertrophy, as well as squamous changes of the urethra (Waltzer, 1981).

Augmented Renal Function

The transient increases in glomerular filtration rate and renal plasma flow during pregnancy have been well summarized by several authors, and are probably secondary to the increase in cardiac output (Davison and Lindheimer, 1978; Kincaid-Smith, 1978; Waltzer, 1981; Zacur and Mitch, 1977). **Glomerular filtration increases by 30% to 50%, and urinary protein excretion increases. The significance of these physiologic changes is apparent when the normal serum creatinine and urea nitrogen values for pregnant women are surveyed** (Table 55.12)**. Values considered normal in non-pregnant women may represent renal insufficiency during pregnancy.**

TABLE 55.12

Average Values for Serum Creatinine and Urea Nitrogen

	NON-PREGNANT FEMALES (mg/dL)	PREGNANT FEMALES (mg/dL)
Serum creatinine	0.7	0.5
Urea nitrogen	13.0	9.0

Data from Davison JM, Lindheimer MD: Renal disease in pregnant women. *Clin Obstet Gynecol* 21:411, 1978.

Davison and Lindheimer (1978) recommend that pregnant patients with serum creatinine levels greater than 0.8 mg/dL or urea nitrogen levels greater than 13 mg/dL undergo further evaluation of renal function. Similarly, **urinary protein in pregnancy is not considered abnormal until more than 300 mg of protein in 24 hours is excreted.**

These significant physiologic changes in pregnancy, which may develop as early as the first trimester, lead to urinary stasis and mild hydroureteronephrosis, and contribute to development of pyelonephritis.

Recent studies of *E. coli* adhesins and their respective specific tissue receptors have established an adhesin-based mechanism for pyelonephritis-induced preterm birth and low birth weight in mice (Kaul et al., 1999). There is a higher incidence of *E. coli*–bearing Dr adhesins during the third trimester of pregnancy in women with gestational pyelonephritis (Nowicki et al., 1994) and an upregulation of Dr adhesin in the kidney, endometrium, and placenta during the third trimester of pregnancy (Martens et al., 1993). When infected intravesically with *E. coli*–bearing Dr adhesin, nearly 90% of mice that were hyporesponsive to bacterial lipopolysaccharide and that had a deficient immune response delivered pre-term. However, only 10% of mice infected with *E. coli* without Dr adhesion delivered pre-term. Also, there was a significant reduction in fetal birth weight in the Dr adhesin–infected group. Bacterial tissue culture showed systemic spread of the *E. coli*–bearing Dr adhesins to the placentae and fetuses.

Complications Associated With Bacteriuria During Pregnancy

Prematurity and Prenatal Mortality

In the pre-antimicrobial era, pregnant women with symptomatic UTIs and bacterial pyelonephritis were reported to have a high incidence of prematurity, low birth weight, and death (Gilstrap et al., 1981). The relationship between asymptomatic bacteriuria and prematurity is less clear. Gilstrap et al. (1981) found no difference in prematurity rates between pregnant patients treated for asymptomatic bacteriuria and non-bacteriuric controls. However, Cunnington's review suggests that ascending GU tract infections may contribute to up to 50% of premature deliveries, especially when they occur before 30 weeks' gestation (Cunnington et al., 2013). **Pregnant women with asymptomatic bacteriuria are at higher risk for developing symptomatic UTIs that result in adverse fetal outcomes, pyelonephritis, and possible maternal sequelae such as sepsis. Therefore all pregnant women with asymptomatic bacteriuria should be treated** (Smaill, 2001).

Maternal Anemia

Although several studies suggest that bacteriuria untreated during pregnancy is associated with maternal anemia, not all studies support this. Some difficulties in interpreting the results of these surveys have been caused by inadequate documentation of bacteriuria. In one survey in which urine cultures were obtained by suprapubic aspiration, the data suggest that pregnant patients requiring three or more treatments for bacteriuria have lower levels of serum hemoglobin and folate than controls (McFadyen et al., 1973). In another study from England, investigators showed a statistically significant difference in the incidence of anemia between 410 bacteriuric pregnant women and 409 control pregnant women (Williams et al., 1973). In this survey, 14.6% of bacteriuric women and 10% of control women were anemic at the first prenatal visit. This separation increased during the third trimester (32 weeks), when 25% of women treated with placebo alone had anemia, but only 16.8% of those women treated with antimicrobial agents had anemia. Furthermore, in the 31 untreated (placebo-treated) bacteriuric women who subsequently developed pyelonephritis, the incidence of anemia was 45.2%. These investigators concluded that “untreated bacteriuria increases the likelihood of developing anemia during pregnancy and that this risk is enhanced by the development of acute pyelonephritis, even if it is treated promptly” (Williams et al., 1973).

Laboratory Diagnosis

Significant false-negative rates occur if screening is conducted by urinalysis or reagent strip testing (McNair et al., 2000; Preston et al., 1999)**. Therefore an initial screening culture should be performed in all pregnant women during the first trimester** (Stenqvist et al., 1989). The US Preventive Services Task Force (USPSTF) recommends screening for asymptomatic bacteriuria with urine culture in pregnant women at 12 to 16 weeks’ gestation or at the first prenatal visit, if later (Lin et al., 2008). If the culture shows no growth, repeat cultures are generally unnecessary because **patients who have no growth in their urine early in their pregnancy are unlikely to develop bacteriuria later** (McFadyen et al., 1973; Norden and Kass, 1968). Pregnant women with a history of recurrent UTI or VUR may benefit from AP (Bukowski et al., 1998).

Management

Selection of an antimicrobial agent to treat the bacteriuria must be made, however, with special considerations given to maternal and fetal toxicity. The physiologic changes of pregnancy such as maternal expanded fluid volume, the distribution of the drug to the fetus, increased renal blood flow, and increased glomerular filtration may decrease the serum drug concentration. **If the culture is positive, special consideration must be given to the selection of antimicrobial agents chosen to treat infection and prevent fetal toxicity. The pathogens are similar to those seen in non-pregnant women** (MacDonald et al., 1983). Table 55.13 lists the antimicrobial agents and dosing for use in pregnancy. The **aminopenicillins and cephalosporins are considered safe and generally effective throughout pregnancy. In patients with penicillin allergy, nitrofurantoin is a reasonable alternative. It may be used safely during the first two trimesters in patients without glucose-6-phosphate dehydrogenase deficiency.** Nitrofurantoin is often used **because fluoroquinolones and TMP-**

SMX are contraindicated in pregnancy. If nitrofurantoin is used, however, this is discontinued at 35 weeks of gestation because of an increased risk of hemolytic anemia in the neonate. If a pregnant woman has a single episode of pyelonephritis or two episodes of cystitis, daily suppression with either nitrofurantoin or cephalexin should be considered until delivery. It is prudent to prescribe a full 3- to 7-day course of therapy in pregnant women.

TABLE 55.13

Oral Antimicrobial Agents Used in Pregnancy

DRUG	DOSAGE	COMMENTS
AGENTS CONSIDERED SAFE		
Penicillins		
Ampicillin	500 mg four times daily	Extensively used
Amoxicillin	250 mg three times daily	Safe and effective
Penicillin V	500 mg four times daily	Used less frequently but achieves excellent urinary levels
Cephalosporins		
Cephalexin	500 mg four times daily	Extensively used
Cefaclor	500 mg four times daily	Somewhat more effective against gram-negative organisms
Nitrofurantoin	100 mg four times daily	May be used during the first two trimesters; may result in hemolytic anemia in patients with G6PD deficiency
AGENTS THAT SHOULD BE AVOIDED		
Fluoroquinolones		Possible damage to immature cartilage
Chloramphenicol		Associated with “gray baby” syndrome
Trimethoprim		Inhibits folic acid metabolism and is thus teratogenic especially with respect to neural tube defects
Erythromycin		Associated with maternal cholestatic jaundice
Tetracyclines		May cause acute liver decompensation in the mother and inhibition of new bone growth in the fetus

G6PD, Glucose-6-phosphate dehydrogenase.

Modified from Schaeffer AJ: Urinary tract infections. In Gillenwater JY, Grayhack JT, Howards SS, et al., editors: *Adult and pediatric urology,* Philadelphia, 2002, Lippincott Williams & Wilkins, pp 211–272.

In 2011 a Cochrane Review completed by Widmer et al. showed that antibiotic treatment of asymptomatic bacteriuria in pregnant women significantly decreases the risk of pyelonephritis and preterm delivery. However, there was not adequate evidence at that time to suggest that a single-dose treatment was as effective as standard conventional treatment (Widmer et al., 2011). A more recent Cochrane review published in 2015 looked at the duration of treatment for asymptomatic bacteriuria (Widmer et al., 2015). The authors looked at 13 studies that included 1622 women and compared single-dose treatment with 4- to 7-day course (short) treatment. The review found that a 7-day regimen was more effective than a 1-day course, especially for preventing a low-birth-weight outcome, but this was based on only one study. There were no differences for other review outcomes such as pyelonephritis and preterm birth. The authors concluded by saying although more trials were needed, women with asymptomatic bacteriuria in pregnancy should be treated with a standard time regimen of antibiotics.

Follow-up cultures should be obtained to document absence of infection. If the culture is positive, the cause of bacteriuria must be determined to be lack of resolution, bacterial persistence, or reinfection. If the infection is unresolved, proper selection and administration of another drug will likely solve the problem. If the problem is bacterial persistence or rapid reinfection, antimicrobial suppression of infection or prophylaxis (Pfau and Sacks, 1992) throughout the remainder of the pregnancy should be considered.

Pregnant women with acute pyelonephritis should be hospitalized and initially treated with parenteral antimicrobial agents until clinical improvement is noted. There is no strong evidence to recommend a specific treatment regimen in pregnant women. β-Lactam antibiotics are commonly used because they are considered relatively safe for the fetus. Carbapenems are generally used in select severe cases including those caused by multidrug-resistant bacteria (Matuszkiewicz-Rowinska et al., 2015). However, older series reported that more than 95% of these patients respond within 24 hours using ampicillin and an aminoglycoside (Cunningham et al., 1973) or cephalosporins (Sanchez-Ramos et al., 1995). Despite known toxicities, a recent study concluded that aminoglycosides, specifically gentamicin, are still used often in pregnant women with UTIs, thus subjecting them unnecessarily to ototoxicity (Kushner et al., 2016). Parenteral treatment should be tailored on the basis of culture sensitivities before transitioning to oral antibiotics. If improvement is not seen within 72 hours of the commencement of antibiotics, a renal ultrasound should be performed to assess for stone, obstruction, or abscess. If there is a strong suspicion of a urologic stone that cannot be seen with ultrasound, a plain radiograph of the abdomen or a low-dose spiral CT should be considered in urgent cases.

A Cochrane review published in 2015 looked at interventions for preventing recurrent UTI during pregnancy. The authors concluded that close surveillance alone was as effective as a daily dose of nitrofurantoin and close surveillance together to prevent recurrent UTIs, although the evidence was low quality. They also found there was a significant reduction in asymptomatic bacteriuria in women who had a high clinic attendance rate and had received nitrofurantoin and close surveillance (Schneeberger et al., 2015).

Medications that are relatively contraindicated during pregnancy include the fluoroquinolones, TMP, chloramphenicol, erythromycin, tetracycline, sulfonamides, and sometimes nitrofurantoin (Nicolle, 1987). Fluoroquinolones are contraindicated because of their effects on immature cartilage. TMP may have teratogenic effects and should be avoided, especially in the first trimester. The “gray baby” syndrome is a toxic effect of chloramphenicol on neonates resulting from the inability of the infant to metabolize or excrete the drug. Erythromycin may cause cholestatic jaundice in the mother. Tetracycline may cause fetal malformations and maternal liver decompensation. Sulfonamides may cause kernicterus and neonatal hyperbilirubinemia and should be avoided in the third trimester. As mentioned earlier, nitrofurantoin can cause hemolytic anemia in mother and child when glucose-6-phosphate dehydrogenase deficiency is present (Nicolle, 1987).

Pregnancy in Women With Renal Insufficiency

With current management of recurrent UTIs, infections alone are not contraindications to pregnancy. In patients who have renal insufficiency with or without UTIs, Davison and Lindheimer (1978) emphasize that renal function should be carefully evaluated through serum creatinine levels and creatinine clearance before a woman is counseled about conceiving or continuing a pregnancy. Although little is known about the outcome of pregnancies with differing degrees of renal insufficiency, it is known that **normal pregnancy is**

rare if the preconception serum creatinine level exceeds 3 mg/dL (about 30 mL/min clearance).

The degree of renal function impairment is the major determinant for pregnancy outcome. **In pregnant women with mild or moderate renal disease (serum creatinine <1.4 mg/dL and from 1.4 mg/dL to 2.4 to 2.8 mg/dL, respectively) the fetal survival rate is only slightly diminished, and irreversible deterioration of maternal renal function is uncommon.** However, the perinatal mortality is approximately four times higher with severe disease. The rate of perinatal morbidity associated with low birth weight or prematurity doubles with mild to moderate maternal renal disease; in moderate to severe disease it doubles once again (Vidaeff et al., 2008).

Key Points: Bacteriuria in Pregnancy

- Screening for bacteriuria via urine culture should be performed in all pregnant women during the first trimester.
- The prevalence of bacteriuria does not change with the occurrence of pregnancy; however, unlike in non-pregnant women, spontaneous resolution of bacteriuria in pregnant women is unlikely.
- All pregnant women with bacteriuria should be treated.
- Bacteriuria more commonly progresses to acute pyelonephritis during pregnancy.

Bacteriuria and Urinary Tract Infections in the Elderly

As the average life expectancy increases, the diagnosis, treatment, and morbidity and mortality of UTIs in the geriatric population will continue to be of utmost importance. In 2012 there were 43.1 million Americans older than 65 years of age (Ortman et al., 2014). By the year 2050, however, the population aged 65 and over in the United States is projected to be 83.7 million. Certainly, this trajectory in population dynamics within the US alone highlights the public health issue inherent to this topic.

Epidemiology

At least 20% of women and 10% of men older than 65 years have bacteriuria that is detected by standard urine culture (Boscia and Kaye, 1987)**. In contrast to young adults, in whom bacteriuria is 30 times more prevalent in women than in men, this ratio in the elderly progressively decreases to 2:1. Most elderly patients with bacteriuria are asymptomatic.**

The prevalence of bacteriuria in the elderly increases with age (Brocklehurst et al., 1968; Sourander, 1966) and concurrent disease and may exceed 50% in selective groups (Boscia and Kaye, 1987; Schaeffer, 1991). Bacteriuria is present in greater than 20% of healthy community-dwelling women older than 80 years of age and in 6% to 15% of community-dwelling men who are older than 75 years of age (Nicolle, 2003). Estimates of bacteriuria in those living in long-term care facilities range from 25% to 50% of women and 15% to 40% of men (Nicolle, 1997). Risk factors can be compounded. In a study of 373 women and 150 men older than 68 years of age, 24% of functionally impaired nursing home residents had bacteriuria compared with 12% of healthy domiciliary subjects (Boscia et al., 1986).

Screening for Bacteriuria

Screening for asymptomatic bacteriuria in elderly residents in the community or long-term care facilities is not recommended (Abrutyn et al., 1994; Boscia et al., 1987; Nicolle et al., 1983, 2005; Nordenstam et al., 1986)**.**

There is no documented relationship between asymptomatic bacteriuria and uncomplicated UTIs and worsening renal function. The treatment of asymptomatic bacteriuria to improve incontinence has not been justified (Baldassarre and Kaye, 1991; Ouslander et al., 1995). Although studies have demonstrated decreased survival in bacteriuric patients compared with non-bacteriuric control subjects, it is unclear whether increased mortality rates and bacteriuria are causally related (Abrutyn et al., 1994; Baldassarre and Kaye, 1991).

Pathogenesis

The pathophysiology of increased susceptibility to bacteriuria/UTIs is multifactorial and poorly understood. **Age-related changes include a decline in cell-mediated immunity, incomplete bladder emptying, neurogenic bladder dysfunction, increased perineal soiling as a result of fecal and urinary incontinence, increased incidence of urethral catheter placement, and, in women, changes in the vaginal environment associated with estrogen depletion** (Arnold et al., 2016; Raz and Stamm, 1993; Schaeffer, 1991).

Bacteriologic characteristics of infection in the elderly differ from those in younger patients (Baldassarre and Kaye, 1991). ***E. coli* remains the most common uropathogen overall, causing 50% to 75% of these infections** (Nicolle, 2001). However, there is a **significant increase in the incidence of *Proteus, Klebsiella, Enterobacter, Serratia,* and *Pseudomonas* spp., as well as enterococci.** One study found that in community-dwelling older women, organisms responsible for asymptomatic bacteriuria include *E. coli* (51.4%), *K. pneumoniae* (4.1%), *Proteus mirabilis* (3.3%), and *Enterococcus faecalis* (2.5%) (Linhares et al., 2013). Enterococci in the elderly tend to resolve without treatment; this is felt to represent colonization (Das et al., 2009). Bacteriuria caused by gram-positive bacteria is much more common in elderly men than in elderly women (Jackson et al., 1962); however, *S. saprophyticus* is not seen in this population. Polymicrobial bacteriuria is also more common among the geriatric population (Nicolle et al., 1987). Cumulatively, the shift in the pattern of uropathogens, the high frequency of polymicrobial infections, and antimicrobial resistance in the elderly are due in large part to an increase in institutionalization and hospitalization, catheterization, and overall antimicrobial usage (Routh et al., 2009).

Diagnosis

In the elderly, UTI symptoms may be more subtle, such as generalized abdominal discomfort or delirium. **Even severe upper tract infections may not be associated with fever or leukocytosis** (Baldassarre and Kaye, 1991). **However, new signs or symptoms localized to the lower urinary tract, specifically dysuria, remain the most important UTI criteria, even in the elderly.** Traditionally, altered mental status has often been attributed to a UTI in the elderly. However, because bacteriuria is more common with age, the mere presence of a positive urine culture in a patient with altered mental status is not tantamount with a UTI. This dilemma makes diagnosing a UTI, particularly in a patient who cannot reliably report symptoms, challenging. **Although it has been common practice to treat elderly bacteriuric patients with antibiotics because of confusion, no data demonstrate treatment improves a patient's condition** (Finucane, 2017).

Because new signs or symptoms localized to the GU tract are most important even in the geriatric population, dizziness and confusion, in the absence of urinary symptoms, should not be attributed to a UTI. Therefore it is not recommended to send urine cultures on patients for nonspecific symptoms or chronic urinary symptoms such as incontinence and frequency, nor for asymptomatic patients (Mody and Juthani-Mehta, 2014; Nicolle, 2002). Sending urine studies in patients with dementia or other impaired mental status (when defining dysuria is difficult) may be of clinical benefit when not responsive to other interventions (i.e., hydration). **If elderly patients experience mental status changes yet no urinary complaints, they should be hydrated then reassessed. If altered mental status and/or change in character of urine persists despite fluid resuscitation, then urine testing should be considered** (see figure at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4194886/) (Mody and Juthani-Mehta, 2014). Finally, obtaining a culture to document clearance of bacteria is never recommended (Mody and Juthani-Mehta, 2014).

A high index of suspicion is warranted when evaluating geriatric patients; therefore diagnosis should rely on the results of a carefully obtained urinalysis and culture. **The presence of greater than 10^5 CFU/mL of urine remains the standard for diagnosis** in patients with clinical signs and symptoms of UTI. However, **counts of 10^2 or more bacteria are clinically significant in catheterized specimens** (Kunin, 1987; Nicolle et al., 2005).

The use of laboratory testing in the diagnosis of UTI in the elderly also poses some challenges. Urinary dipstick testing for leukocyte esterase, nitrites, or both has a different specificity and sensitivity depending on the clinical population. Sensitivity and specificity for a positive dipstick test in older adults is 82% (95% CI 74%–92%) and 71% (95% CI 55%–71%), making the urine dipstick a more valuable test to rule out UTI than diagnosing its presence (Deville et al., 2004; Kunin, 1994). These data are linked to the fact that, unlike in younger adults, pyuria and in turn the presence of leukocyte esterase, has been shown to be an inaccurate predictor of bacteriuria in the elderly. **Pyuria is common in elderly patients, and pyuria alone is not a good predictor of bacteriuria nor an indication for antimicrobial treatment in the elderly population** (Nicolle et al., 2005; Ouslander et al., 1996). Accordingly, Boscia et al. (1989) reported that more than 60% of women with pyuria of 10 WBCs/mm^3 or greater (noted in midstream specimens) did not have a concurrent bacteriuria. However, **the absence of pyuria was a good predictor of the absence of bacteriuria**, and this accounts for the high specificity associated with dipstick testing.

Finally, declining functional and mental status in elderly adults, as well as a potentially difficult body habitus, often makes obtaining a true midstream clean-catch urine specimen extremely challenging. In institutionalized elderly patients and those with limited dexterity, a catheterized specimen may be the only way to obtain an uncontaminated urine specimen (Nicolle, 2002; Nicolle et al., 2005).

Because urinary tract abnormalities can predispose to and complicate the management and sequela of bacteriuria in the elderly, a thorough urologic evaluation is warranted. Renal dysfunction, calculi, hydronephrosis, urinary retention, neurogenic bladder dysfunction, and other abnormalities should be identified by serum creatinine measurement, CT, ultrasonography, urodynamics (UDS), and/or cystoscopy. The timing and sequence of these tests should be dictated by the clinical setting.

Bacteriuria that leads to UTIs in elderly subjects in the presence of underlying structural urinary tract abnormalities (e.g., obstruction with hydronephrosis) or systemic conditions (e.g., severe diabetes mellitus) are clinically significant, can lead to renal failure, and require prompt therapy. In addition, UTIs caused by urea-splitting bacteria, such as *Proteus* or *Klebsiella* species that cause formation of infection stones, may also lead to severe renal damage.

Sepsis and its sequelae (sepsis syndrome and septic shock) are increasingly common in the elderly. Risk factors include the aggressive use of catheters (Kunin et al., 1992) and other invasive equipment, implantation of prosthetic devices, and the administration of chemotherapy to cancer patients or corticosteroids in other immunosuppressed patients. In addition, modern medical care has given longer life spans to the elderly and other populations of patients with metabolic, neoplastic, or immunodeficiency disorders who remain at increased risk for infection.

Management

Prospective randomized comparative trials of antimicrobial or no therapy in elderly male and female nursing home residents with asymptomatic bacteriuria consistently document no benefit of antimicrobial therapy. On the contrary, treatment with antimicrobial therapy increases the occurrence of adverse drug effects and reinfection with resistant organisms and increases the cost of treatment. **Therefore asymptomatic bacteriuria in elderly residents of long-term care facilities should not be treated with antimicrobial agents.**

The McGeer infection surveillance definitions provide standardized criteria for infections that commonly occur in residents of aged-care homes. The criteria to be diagnosed with a UTI include a combination of clinical signs and microbiology (Stone et al., 2012)**. The criteria required vary, depending on whether the patient has an indwelling catheter or not. Critics of the McGeer criteria point out that the ability to interpret the clinical signs in those who are cognitively impaired is limited (**Ryan et al., 2018; **Table 55.14).**

TABLE 55.14

Surveillance Definitions for Urinary Tract Infections

CRITERIA
A. For residents without an indwelling catheter (both criteria 1 and 2 must be present)
1. At least 1 of the following sign or symptom subcriteria
a. Acute dysuria or acute pain, swelling, or tenderness of the testes, epididymis, or prostrate
b. Fever or leukocytosis and at least 1 of the following localizing urinary tract subcriteria
i. Acute costovertebral angle pain or tenderness
ii. Suprapubic pain
iii. Gross hematuria
iv. New or marked increase in incontinence, urgency, or frequency
c. In the absence of fever or leukocytosis, then 2 or more of the following

localizing urinary tract subcriteria
        - i. Suprapubic pain
        - ii. Gross hematuria
        - iii. New or marked increase in incontinence
        - iv. New or marked increase in urgency
        - v. New or marked increase in frequency
    2. One of the following microbiologic subcriteria
        - a. At least 10^5 CFU/mL of no more than 2 species of microorganisms in a voided urine sample
        - b. At least 10^2 CFU/mL of any number of organisms in a specimen collected by in-and-out catheter[5]

B. For residents with an indwelling catheter (both criteria 1 and 2 must be present)
    1. At least 1 of the following sign or symptom subcriteria
        - a. Fever, rigors, or new-onset hypotension, with no alternate site of infection
        - b. Either acute change in mental status or acute functional decline, with no alternate diagnosis and leukocytosis
        - c. New-onset suprapubic pain or costovertebral angle pain or tenderness
        - d. Purulent discharge from around the catheter or acute pain, swelling or tenderness of the testes, epididymis, or prostate
    2. Urinary catheter specimen culture with at least 10^5 CFU/mL of any organism(s)

Comment: A diagnosis of UTI can be made without localizing symptoms if a blood culture isolate is the same as the organism isolated from the urine and there is no alternate site of infection.

From McGeer Criteria, p68, Ryan, Gillespie et al. 2018.

If patients have lower tract symptoms and symptoms are mild, it is prudent to wait for urine culture before treatment. For those elderly patients who require immediate treatment, empirical antibiotics should be started. Traditionally, 7 days of therapy has been recommended. However, a recent Cochrane review of the antibiotic duration for treating uncomplicated symptomatic UTIs in the elderly included 15 studies totaling 1644 women and showed no difference in short-term clinical failure between short-course (3–6 days) and long-course (7–14 days) oral antibiotic regimens. The rate of persistent UTI was lower with short-term therapy compared with single-dose (Lutters and Vogt-Ferrier, 2008). For individuals with fever or more severe systemic infection, 10 to 14 days of therapy was recommended. The goal in this population was to eliminate symptoms but not sterilize the urine (McMurdo and Gillespie, 2000).

The elderly population is more susceptible than young patients to the

toxic and adverse effects of antimicrobial agents (Boscia et al., 1986; Carty et al., 1981; Grieco, 1980). The metabolism and excretion of antimicrobial agents may be impaired, and the resulting increased serum levels can further damage renal function. Interactions with other medications can occur (Stahlmann and Lode, 2003). The safety margin between therapeutic and toxic doses is significantly narrowed. Therefore antimicrobial agents must be used judiciously, and dosing and drug levels should be carefully monitored. **The recent black box warning pertaining to fluoroquinolones urges caution in patients older than 60, in whom the risk of tendon rupture is greatest.** See the Management section for further discussion of antibiotic prescribing regimens/considerations for complicated and uncomplicated infections.

Key Points: Bacteriuria in the Elderly

- Screening for bacteriuria is not recommended in elderly patients because there is no relationship between asymptomatic bacteriuria and uncomplicated UTIs and deteriorating renal function; asymptomatic bacteriuria should not be treated.
- Infections of the urinary tract may present as subtle signs, and a high index of suspicion is often required for diagnosis.
- Treatment of symptomatic UTI requires modifications for physiologic and pathophysiologic conditions of the elderly.
- Obtaining a urine culture to document clearance of bacteriuria is not recommended.

Catheter-Associated Urinary Tract Infection

Guidelines from the CDC define a CAUTI as a UTI after placement of an indwelling urinary catheter for more than 2 days (Centers for Disease Control and Prevention: Urinary Tract Infection, 2015). To be diagnosed with a CAUTI, patients must have one symptom of a UTI (suprapubic tenderness, CVA tenderness, urinary frequency/urgency/dysuria, or fever >100.4°F) and a urine culture with a single organism more than 100,000 CFU/mL.

Catheter-associated bacteriuria is widely recognized as the most common hospital-acquired infection. The development of bacteriuria in the presence of an indwelling catheter is inevitable and occurs at an incidence of approximately 10% per day of catheterization. Sterile and clean intermittent catheterization has been associated with rates of bacteriuria ranging from 1% to 3% per catheterization (Warren, 1997)**. The most important risk factors associated with increased likelihood of developing catheter-associated bacteriuria are duration of catheterization, female gender, absence of systemic antimicrobial agents, and catheter-care violations** (Stamm, 1991). **Most patients with catheter-associated bacteriuria are asymptomatic.** In patients with short-term catheter placement, only 10% to 30% of bacteriuric episodes produce typical symptoms of acute infection (Haley et al., 1981; Hartstein et al., 1981). Similarly, although patients with long-term catheters are bacteriuric, the incidence of febrile episodes occurs at a rate of only 1 per 100 days of catheterization (Warren, 1991).

Each CAUTI is estimated to cost between $589 and $758 (Anderson et al., 2007; Tambyah et al., 2002). In patients requiring intensive care, the cost is roughly $2000 per nosocomial UTI (Chen et al., 2009). The nosocomial costs for *E. coli* infections with relatively susceptible strains are considerably lower than for those caused by resistant gram-negative bacteria, which often require expensive parenteral antimicrobial therapy (Tambyah et al., 2002).

In 2008 the Center for Medicare and Medicaid Services (CMS) announced that it will no longer reimburse hospitals for the extra costs resulting from CAUTIs. Judicious use of indwelling Foley catheters in perioperative patients helps to prevent CAUTI. Current recommendations for perioperative use of an indwelling urinary catheter include intraoperative urine output monitoring, prolonged surgeries, and urologic surgeries (Gould, 2009). Limiting the duration of indwelling catheters in these patients is critical. Large nationwide hospital initiatives have helped to reduce the CAUTI rates. The Mayo Clinic reported a 70% decrease in their CAUTI rate over 1 year. They described their protocol as the bundled 6-C CAUTI approach: consider (appropriate placement and daily need for indwelling catheter), connect, clean (catheter care), closed (maintain closed system), call (irrigation when necessary) and culture (only for indication) (Sampathkumar et al., 2016).

Pathogenesis

Bacteria enter the urinary tract of a catheterized patient by several routes. **Bacteria can be introduced at the time of initial catheter placement** by either mechanical inoculation of urethral bacteria or contamination from poor technique. **Subsequently, the bacteria most commonly gain access via a periurethral or intraluminal route** (Stamm, 1991). In women, periurethral entry is the most prevalent. Daifuku and Stamm (1984) found that among 18 women who developed catheter-associated bacteriuria, 12 had antecedent urethral colonization with the infecting strain. **Bacteria may also enter the drainage bag and follow the intraluminal route to the bladder.** This route is particularly common in patients who are clustered among other patients with indwelling catheters (Maizels and Schaeffer, 1980; Tambyah et al., 1999).

The urinary catheter system provides a unique environment that allows for two distinct populations of bacteria: those that grow within the urine and those that grow on the catheter surface. A bacterial **biofilm** represents a microbial environment of microorganisms embedded in an extracellular matrix of bacterial products and host components that often lead to catheter encrustation (Bonadio et al., 2001; Stamm, 1991). The bacterial biofilm prevents antibiotic contact with the bacteria and can result in CAUTI and antibiotic resistance (Chenoweth and Saint, 2016). Certain bacteria, particularly of the *Pseudomonas* and *Proteus* species, are adept at biofilm growth, which may explain their higher incidence in this clinical setting (Mobley and Warren, 1987). The uropathogens isolated from the catheterized urinary tract often differ from those found in uncatheterized ambulatory patients. *E. coli* is still the most common organism isolated, but *Pseudomonas*, *Proteus*, and *Enterococcus* spp. are prevalent (Warren, 1991). In patients with long-term catheterization (more than 30 days), the bacteriuria is usually polymicrobial, and the presence of four or five pathogens is not uncommon (Warren et al., 1982). Although certain species may persist for long periods, the bacterial populations in these patients tend to be dynamic.

Clinical Presentation

Most patients are asymptomatic. Suprapubic discomfort and development of fever, chills, or flank pain may indicate a symptomatic UTI.

Laboratory Diagnosis

Significant bacteriuria in patients with catheters is present when greater than 100 CFU/mL is present, because even this low level progresses to greater than 10^5 CFU/mL in almost all patients (Maizels and Schaeffer, 1980; Stark and Maki, 1984). Pyuria is not a discriminate indicator of infection in this population.

Management

Careful aseptic insertion of the catheter and maintenance of a closed dependent drainage system are essential to minimize development of bacteriuria. The catheter-meatal junction should be cleaned daily with water, but antimicrobial agents should be avoided because they lead to colonization with resistant pathogens, such as *Pseudomonas*.

Incorporation of silver oxide (Schaeffer et al., 1988) or silver alloy (Saint et al., 1998) into the catheter and hydrogen peroxide into the drainage bag has been reported to decrease the incidence of bacteriuria in some studies (Schaeffer et al., 1988), but not in other populations (Stamm, 1991). **The major benefit of silver alloy is that it decreases the likelihood of bacteriuria in hospitalized adults catheterized for the short term** (Brosnahan et al., 2004; Newton et al., 2002; Saint et al., 2000).

If an asymptomatic catheterized patient has had an indwelling catheter for 3 or more days and will have the catheter removed, a dipstick test can be used to rule out bacteriuria (Tissot et al., 2001). **Concurrent administration of systemic antimicrobial agents transiently decreases the incidence of bacteriuria associated with short-term catheterization, but after 3 to 4 days the incidence of bacteriuria is similar to the rate in catheterized patients not**

taking systemic antimicrobials agents, and the prevalence of resistant bacteria and side effects is substantial. Therefore this practice is not recommended. The concept of instilling nonvirulent bacteria into the bladder to completely block colonization and infection by pathogens has been tested in patients with SCI (Hull et al., 2000). Patients successfully colonized with the nonvirulent strain had reduced symptomatic UTI and a subjective improvement in quality of life.

Patients with indwelling catheters should be treated only if they become symptomatic (e.g., febrile). Urine cultures should be performed before initiating antimicrobial therapy. The antimicrobial agent should be discontinued within 48 hours of resolution of the infection. Because the catheter has been indwelling, encrustation may shelter bacteria from the antimicrobial agent; therefore the catheter should be changed.

Key Points: Catheter-Associated Bacteriuria

- Careful aseptic insertion of the catheter and maintenance of a closed, dependent drainage system are essential to minimize development of bacteriuria.
- The development of catheter-associated bacteriuria is inevitable.
- Only symptomatic CAUTIs require treatment.

Management of Urinary Tract Infections in Patients With Spinal Cord Injury

Patients with SCI have unique characteristics that affect the risk, diagnosis, and management of UTIs, all of which are considered complicated. **Of all patients with bacteriuria, no group compares in severity and morbidity with those who have SCI.** Nearly all these patients require catheterization early after their injuries because of bladder overactivity or flaccidity, and significant numbers develop ureterectasis, hydronephrosis, VUR, and renal calculi. Bacteriologic and urodynamic advances in the management of these patients have greatly reduced their morbidity and mortality.

Epidemiology

Before the advent of CIC and modern antibiotics, UTI and renal failure accounted for the great majority of deaths in the SCI population (Barber and Cross, 1952). The National Spinal Cord Injury Statistical Center published a report in 2012 stating that GU infections account for only 3% of deaths in the SCI population, the 11th most common cause of deaths; the advent of CIC and antibiotics has clearly decreased the morbidity attributed to UTIs and renal failure, as compared with mid–20th century statistics.

UTIs are among the most common urologic complications of SCI. It has been estimated that approximately 33% of patients with SCI have bacteriuria at any time (Stover et al., 1989) and that eventually almost all patients with SCI will become bacteriuric; many will suffer significant morbidity and mortality. One prospective study of patients on intermittent catheterization or condom catheterization reported an incidence of significant bacteriuria (18 episodes per person per year) and an annual incidence of febrile UTIs of 1.8 per person per year (Waites et al., 1993a). In addition, **UTI is the most common cause of fever in the patient with SCI** (Beraldo et al., 1993). **The 1992 National Institute on Disability and Rehabilitation Research Consensus Conference examined the problems associated with UTIs in patients with SCI** (National Institute on Disability and Rehabilitation Research, 1993)**. Among the risk factors identified were impaired voiding, overdistention of the bladder, elevated intravesical pressure, increased risk of urinary obstruction, VUR, urinary**

tract instrumentation, and presence of stones. Other factors that have been implicated are decreased fluid intake, poor hygiene, perineal colonization, decubiti, and other evidence of local tissue trauma, as well as reduced host defense associated with chronic illness (Gilmore et al., 1992; Waites et al., 1993a).

Pathogenesis

The method of bladder management has a profound impact on the incidence of UTI. The National Institute on Disability and Rehabilitation Research Consensus Conference noted that indwelling catheters were most likely to lead to UTI and that the majority of patients with an indwelling catheter for 30 days are bacteriuric (National Institute on Disability and Rehabilitation Research, 1993). Suprapubic catheters and indwelling urethral catheters eventually have an equivalent infection rate (Biering-Sorensen, 2002; Kunin et al., 1987; Tambyah and Maki, 2000). However, the onset of bacteriuria may be delayed using a suprapubic catheter compared with a urethral catheter. During a 2-year period, 170 patients with SCI were evaluated regarding type of urinary drainage and infection (Warren et al., 1982). In patients using indwelling urethral catheters, all urine cultures were positive. The corresponding values for the suprapubic catheter group were 44%. Condom drainage systems are also associated with an incidence of bacteriuria from 63% (Dukes, 1928) to almost 100% (Pyrah et al., 1955).

Since its introduction by Lapides et al. (1972), clean (but not sterile) intermittent catheterization (CIC) has dramatically changed the management of patients with SCI. **Although never rigorously compared with indwelling urethral catheterization, CIC has been shown to decrease lower urinary tract complications by maintaining low intravesical pressure and by reducing the incidence of stones** (Stover et al., 1989). CIC also appears to reduce complications associated with an indwelling catheter, such as UTI, fever, bacteremia, and local infections such as epididymitis and prostatitis. Weld and Dmochowski (2000) followed 316 patients with SCI (who had received different bladder management) for a mean of 18.3 years and recorded all complications. The CIC group had statistically significantly lower complication rates compared with the urethral catheterization group and no significantly higher complication rates relative to all other management methods for each type of complication studied. Thus it is generally agreed that **CIC places patients with SCI at the**

lowest risk for significant long-term urinary tract complications (Stamm, 1975).

There is conflicting evidence over the value of sterile versus nonsterile or "no touch" methods of CIC. Some studies have reported a lower incidence of infection in patients treated with sterile techniques (Foley, 1929), whereas others have not (Nyren et al., 1981; Pyrah et al., 1955). Bennett et al. (1997) reported on a sterile method of CIC that uses an introducer tip to bypass the distal 1.5 cm of the urethra and showed a significant decrease in UTI. Different types of catheters have been used for CIC. The low-friction catheters may be less traumatic for the urethra (Casewell and Phillips, 1977; Garibaldi et al., 1980), but their impact on bacteriuria and UTI has yet to be proven. Cardenas et al. (2011) looked at the time to first UTI in SCI patients using hydrophilic catheters compared with standard non-hydrophilic catheters. They reported that half of each group experienced symptomatic UTI within a 20-day period, although the hydrophilic group had a longer time before UTI.

Clinical Presentation

The majority of patients with SCI with bacteriuria are asymptomatic. Many are managed with CIC, suprapubic catheters, and indwelling Foley catheters, which can lead to asymptomatic bacteriuria. Asymptomatic bacteriuria should not be treated in the patient with SCI (Nicolle et al., 2005; Vigil and Hickling, 2016)**. Furthermore, asymptomatic patients with SCI who use indwelling, condom, or intermittent catheters should not be screened with urinalysis or urine culture. There is no standard definition for UTI in patients with SCI. Because of a loss of sensation, patients usually do not experience frequency, urgency, or dysuria, making the diagnosis of UTI a challenge in this population. More often, they complain of flank, back, or abdominal discomfort, leakage between catheterizations, increased spasticity, malaise, lethargy, and/or cloudy, malodorous urine. As noted earlier, UTI is the most common cause of fever in this population.**

Bacteriology and Laboratory Diagnosis

Urinalysis will show bacteriuria and pyuria. Pyuria is not diagnostic of infections because it may occur from the irritative effects of the catheter. The National Institute on Disability and Rehabilitation Research Consensus Statement recommended criteria for the diagnosis of significant bacteriuria in spinal cord–injured patients (National Institute on Disability and Rehabilitation Research, 1993). Any detectable bacteria from indwelling or suprapubic catheter aspirates was considered significant because the majority of patients with an indwelling catheter and low-level bacteriuria showed an increase to greater than 10^5 CFU/mL within a short period of time (Cardenas and Hooton, 1995). For patients on CIC, greater than or equal to 10^2 CFU/mL was considered significant. For catheter-free males, a clean voided specimen showing greater than or equal to 10^4 CFU/mL was considered significant.

Bacteriuria in patients with SCI differs from that in patients with intact spinal cords with regard to cause, complexity, and antimicrobial susceptibility and is influenced by the type and duration of catheterization. *E. coli* is isolated in approximately 20% of patients. Enterococci, *P. mirabilis*, and *Pseudomonas* spp. are more common in patients with SCI than in patients with intact spinal cords. Other common organisms are *Klebsiella* spp., *Serratia* spp., *Staphylococcus*, and *Candida* spp. Most bacteriuria in short-term catheterization is single-organism, whereas patients catheterized for longer than a month usually demonstrate a polymicrobial flora caused by a wide range of gram-negative and gram-positive bacterial species (Edwards et al., 1983).

Management

As a result of the diverse flora and high probability of bacterial resistance, a urine culture must be obtained before initiating empirical therapy. For afebrile patients, β-lactams, TMP-SMX, and nitrofurantoin can be used while awaiting culture results. **An oral fluoroquinolone may considered as second-line option, given the concerns about resistance patterns and side effects with this class of antibiotics** (Cardenas and Hooton, 1995). An indwelling catheter should be changed to ensure maximal drainage and eliminate bacterial foci in catheter encrustations. **Patients with SCI and fever or chills are usually admitted and treated with a parenteral aminoglycoside and either a penicillin or a third-generation cephalosporin** (Cardenas and Hooton, 1995). In this patient population consultation with a physician with expertise in antimicrobial management may be necessary, especially in a patient with recurrent infections.

If clinical improvement does not occur within 24 to 48 hours, repeat culture and adjustment of antimicrobial therapy based on the initial culture and susceptibility should be performed. Imaging studies should be obtained to rule out obstruction, stones, and abscess. Post-therapy cultures are usually not necessary because asymptomatic recolonization is common and not clinically significant. However, if a urea-splitting bacterium is identified, a follow-up culture should be obtained to ensure its eradication. Bladder irrigation with saline or antibiotic solutions (Waites et al., 2006) has not traditionally been recommended because the rates of catheter-associated bacteriuria and UTI were not reduced with such methods. However, Cox et al. reported in 2017 on 22 patients (cause of NGB was 63.6% SCI) who underwent gentamicin bladder installations. Patients had fewer symptomatic UTIs and underwent fewer courses of oral antibiotics after initiating gentamicin irrigations. In addition, the proportion of multidrug-resistant organisms in urine cultures decreased (Cox et al., 2017).

AP is not supported for patients who have neurogenic bladder caused by SCI (Morton et al., 2002; Vigil and Hickling, 2016). AP did not significantly decrease symptomatic UTIs and resulted in an approximately twofold increase in antimicrobial-resistant bacteria (Nicolle et al., 2019).

Patients with SCI with recurrent symptomatic UTIs should undergo urinary tract imaging and urodynamic testing and a review of their bladder management program. Particular attention should be given to catheter drainage, intermittent catheterization techniques, and frequency of intermittent catheterization or voiding schedule (Cardenas and Hooton, 1995). **Recurrent UTIs may be associated with high storage pressures, and intervention to lower storage pressure may decrease the incidence of symptomatic UTI. Evidence from studies in patients with SCI suggests that bladder catheterization for longer than 10 years is associated with an increased risk of carcinoma of the bladder.** West et al. (1999) examined two databases with more than 33,000 patients with SCI, and over a 5-year period identified 130 patients with bladder cancer (0.4%). Several risk factors for bladder cancer have been proposed. Vereczky et al. (cited in Weyrauch and Bassett, 1951) tested different risk factors based on the outcome of 153 patients with SCI, of which 7 were diagnosed with bladder cancer. Upon identification of 31 possible predictors, only duration of catheterization was significant. **Chronic infection and inflammation of the bladder mucosa could be the carcinogenic stimulus in these patients** (Pyrah et al., 1955)**. Nitrosamines produced in infected urine have also been implicated** (Najenson et al., 1969).

Key Points: Management of Urinary Tract Infection in Patients With Spinal Cord Injury

- The majority of patients with SCI with bacteriuria are asymptomatic. Only symptomatic patients require therapy.
- Patients with SCI and UTI commonly experience fever; flank, back, or abdominal discomfort; leakage between catheterizations; increased spasticity; malaise; lethargy; and/or cloudy, malodorous urine.
- Urine culture before the initiation of empirical therapy is essential because patients with SCI often have evidence of diverse flora with a high probability of bacterial resistance.
- CIC places patients with SCI at the lowest risk for significant long-term urinary tract complications.
- Chronic infection can be carcinogenic.

Kidney Transplant Recipients

There is no current consensus on the role of antibiotics in renal transplant patients with asymptomatic bacteriuria. The IDSA guideline published in 2005 made no recommendation because of insufficient evidence (Nicolle et al., 2005). In the update to this guideline published in 2019, the recommendation is not to screen or treat asymptomatic bacteriuria if the transplant occured more than 1 month prior (Nicolle et al., 2019). In 2013 The American Society of Transplantation Infectious Diseases Community of Practice recommended not treating asymptomatic bacteriuria after 3 months post-transplantation, except in those patients who had a rise in serum creatinine. If the kidney donor has asymptomatic bacteriuria at the time of transplantation, the recipient should be treated. Also, transplant recipients usually receive TMP-SMX for PCP prophylaxis, which can reduce the chance of UTIs (Parasuraman et al., 2013).

In 2018 a Cochrane Review looked at antibiotics for asymptomatic bacteriuria in kidney transplant recipients (Coussement et al., 2018). Asymptomatic bacteriuria occurs in 17% to 51% of kidney transplant recipients and is thought to increase the risk for eventual UTI. The data only included two studies, totaling 212 patients, and excluded those patients with indwelling urethral catheters or ureteral stents. Because of the limited data in the Cochrane Review, the authors concluded there was insufficient evidence to support routine antibiotic treatment of asymptomatic bacteriuria in renal transplant patients. Furthermore, they stated it is unclear if screening for asymptomatic bacteriuria with urine cultures should be performed.

Whether to treat asymptomatic bacteriuria in renal transplant patients remains controversial.

Because of the immunosuppressed state of a kidney transplant recipient, particularly early in the first few months, recognition and treatment of UTI in this population is paramount and may be critical for graft survival. **Transplant recipients are at higher risk for VUR. Risk factors for infection include female gender, diabetes, cadaveric graft, two episodes of asymptomatic bacteriuria, and prolonged hemodialysis before transplantation** (Castaneda et al., 2013). Treatment duration, particularly in the early post-transplantation period (6 months), is usually 14 days for uncomplicated UTIs and 21 to 28 days for complicated UTIs (Säemann and Hörl, 2008).

Antimicrobial Prophylaxis for Common Urologic Procedures

Principles of Surgical Antimicrobial Prophylaxis

The prior urologic best practice statement (BPS) was written in 2008 and validated in 2011. There has been a great deal of effort placed on examining AP over the last decade and the latest BPS published in 2019 should update the practicing urologist. Surgical AP entails treatment with an antimicrobial agent before and for a *limited* time after a procedure to prevent local or systemic postprocedural infections. This is in contrast to antimicrobial treatment, which uses an antimicrobial agent to eradicate a suspected or documented infection.

The 2019 BPS recommends consideration of periprocedural AP for all urologic procedures in which a tissue barrier break will occur. For most procedures, prophylaxis should be initiated within 60 minutes of the procedure (Bratzler et al., 2004). When used as AP, vancomycin and fluoroquinolones should be initiated within 120 minutes of the procedure. Single-dose AP is most appropriate in the majority of uncomplicated urologic surgery. **Efficacious levels should be maintained for the duration of the procedure and, in only special circumstances, a limited time (24 hours, at most) after the procedure** (Bratzler and Houck, 2004). Although prospective studies addressing prophylaxis for urologic procedures exist, most focus on only a narrow spectrum of procedures. However, application of the principles of these studies with additional consideration of the patient and the type of procedure provides a framework for determining when and what type of AP may be indicated. The AP agent chosen should target the likely local organisms and be supported by sensitivities reflected in local antibiograms; cost and safety should be part of the decision-making process. An additional, nontraditional type of prophylaxis in urology entails periprocedural treatment of the urinary tract with an antimicrobial agent to prevent local or systemic sequelae from the manipulation of colonized hardware such as stents or urethral catheters.

A wide array of patients undergo invasive procedures in urology. Two important considerations when assessing the need for AP are the ability of a

host to respond to bacteriuria or bacteremia and the sequelae of a possible infection. Additional considerations include the likelihood of bacterial invasion at the surgical site and possible sequelae. Factors that affect the host's ability to respond to infection include advanced age, anatomic anomalies, poor nutritional status, smoking, chronic corticosteroid use, other concurrent medication use, and immunodeficiency, such as untreated HIV infection (Box 55.13). In addition, chronic indwelling hardware, infected endogenous material such as stones, distant infectious sites, and prolonged hospitalizations also increase the risk of infectious complications, by increasing the local bacterial concentration and/or altering the spectrum of bacterial flora.

Box 55.13

Host Factors That Increase the Risk of Infection

Advanced age
Anatomic anomalies
Poor nutritional status
Smoking
Chronic corticosteroid use
Immunodeficiency
Chronic indwelling hardware
Infected endogenous/exogenous material
Distant coexistent infection
Prolonged hospitalization

Data from Cruse PJ: Surgical wound infection. In Wonsiewicz MJ, editor: *Infectious disease,* Philadelphia, 1992, WB Saunders, pp 758–764; Mangram AJ, Horan TC, Pearson ML, et al.: Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. *Infect Control Hosp Epidemiol* 20:250–278; quiz 279–280, 1999.

The type of procedure will also help direct the timing, duration, and spectrum of AP needed (see Table 55.15 for a summary of AP recommendations). Consideration should be given to the extent of the local tissue injury incurred and the anticipated type of flora at the site. The choice of AP agent should consider the patient's comorbidities, allergies, and the specific AP risk. As stated earlier in the chapter, the FDA issued a black box warning for quinolones because of serious side effects and specifically discouraged their use in treating uncomplicated cystitis; this must be kept in mind while considering use of fluoroquinolones for AP.

TABLE 55.15

Recommended Antimicrobial Prophylaxis for Urologic Procedures

---

PROCEDURE	LIKELY ORGANISMS	PROPHYLAXIS INDICATED	ANTIMICROBIAL(S) OF CHOICE	ALTE ANTI IF RE
LOWER TRACT INSTRUMENTATION				
Cystourethroscopy with minor manipulation, break in mucosal barriers, biopsy, fulguration, etc.; clean-contaminated	GNR, rarely enterococci[†]	Uncertain[§]; consider host-related risk factors. Increasing invasiveness increases risk of SSI	TMP-SMX, Amoxicillin/Clavulanate	1st/2nd Cephal Amino (Aztre Ampic
Transurethral cases: e.g. TURP, TURBT, laser enucleative and ablative procedures, etc.; clean-contaminated[‖]	GNR, rarely enterococci	All cases	Cefazolin, TMP-SMX	Amoxi Amino (Aztre Ampic
Prostate brachytherapy or cryotherapy; clean-contaminated	*S. aureus*, skin; GNR	All cases	Cefazolin	Clinda
Transrectal prostate biopsy; contaminated	GNR, anaerobes[††]; consider MDR coverage, if risks of systemic antibiotics within 6	All cases	Fluoroquinolone, 1st/2nd/3rd gen. Cephalosporin (ceftriaxone commonly used) + Aminoglycoside	Az Ma ID

	months, international travel, healthcare worker			
UPPER TRACT INSTRUMENTATION				
Percutaneous renal surgery; e.g. PCNL; clean-contaminated	GNR, rarely enterococci, and skin[‡‡], *S. aureus*	All cases	1st/2nd gen. Cephalosporin, Aminoglycoside (Aztreonam[¥]) + Metronidazole, or Clindamycin	Ampic
Ureteroscopy, all indications; clean-contaminated	GNR, rarely enterococci	All cases; of undetermined benefit for uncomplicated diagnostic only procedures	TMP-SMX, 1st/2nd gen. Cephalosporin	Amino (Aztre Ampic Cephal Amoxi
OPEN, LAPAROSCOPIC OR ROBOTIC SURGERY				
Without entering urinary tract, e.g. adrenalectomy, lymphadenectomy, retroperitoneal or pelvic; clean	*S. aureus*, skin	Consider in all cases; may not be required	Cefazolin	Clinda
Penile surgery, e.g. circumcision, penile biopsy, etc.; clean-contaminated	*S. aureus*	Likely not required		
Urethroplasty; reconstruction anterior urethra, stricture repair, including urethrectomy; clean; contaminated; controlled entry into the urinary tract	GNR, rarely enterococci, *S. aureus*	Likely required	Cefazolin	Ce Ce An
Involving	GNR *(E. coli)*,	All cases	Cefazolin, TMP-SMX	Ampic

controlled entry into urinary tract e.g. renal surgery, nephrectomy, partial or otherwise, ureterectomy pyeloplasty, radical prostatectomy; partial cystectomy, etc.; clean-contaminated	rarely enterococci			Amino (Aztre Metro Clinda
Involving small bowel (i.e. urinary diversions), cystectomy with small bowel conduit, other GU procedures; uretero-pelvic junction repair, partial cystectomy, etc.; clean-contaminated	Skin, *S. aureus*, GNR, rarely enterococci	All cases	Cefazolin	Clinda amino Cefuro genera cephal Amino combi lactam Metro
Involving large bowel[§§]; colon conduits; clean-contaminated	GNR, anaerobes	All cases	Cefazolin + Metronidazole, Cefoxitin, Cefotetan, or Ceftriaxone + Metronidazole, Ertapenem NB: these IV agents are used along with mechanical bowel preparation and oral antimicrobial (neomycin sulfate + erythromycin base or neomycin sulfate + metronidazole)	Ampic Ticarc Piperc
Implanted	GNR, *S.*	All cases	Aminoglycoside	Amino

prosthetic devices: AUS, IPP, sacral neuromodulators; clean	*aureus*, with increasing reports of anaerobic, and fungal organisms		(Aztreonam[¥]) + 1st/2nd gen. Cephalosporin or Vancomycin[χ]	lactam includi Ampic Ticarci Tazoba
Inguinal and scrotal cases; e.g. radical orchiectomy, vasectomy, reversals, varicocelectomy, hydrocelectomy, etc.; clean	GNR, *S. aureus*	Of increased risk; all cases	Cefazolin	Ampic
Vaginal surgery, female incontinence, e.g. urethral sling procedures, fistulae repair, urethral diverticulectomy, etc.; clean-contaminated	*S. aureus*, streptococci, enterococci, vaginal anaerobes; skin	All	2nd gen. Cephalosporin (Cefoxitin, Cefotetan) provides better anaerobic coverage than 1st gen. cephaloporins; however, Cefazolin is equivalent coverage for the vaginal anaerobes in sling procedures	Ampic Amino Aztreo Metron Clinda
OTHER				
Shock-wave lithotripsy; clean	GNR, rarely enterococci; GU pathogens	Only if risk factors	If risks, consider TMP-SMX, 1st gen. Cephalosporin (Cefazolin), 2nd gen. Cephalosporin (Cefuroxime), Aminopenicillin combined with a β-lactamase inhibitor + Metronidazole	1st/2nd Amoxi Ampic Amino (Aztre Clinda

[†] GU GNR: Common urinary tract organisms are *E. coli*, *Proteus* spp, *Klebsiella* spp, and GPC *Enterococcus*.

[§] If urine culture shows no growth prior to the procedure, antimicrobial prophylaxis is not necessary.

[¶] Or full course of culture-directed antimicrobials for documented infection (which is treatment, not prophylaxis).

[¥]Aztreonam can be substituted for aminoglycosides in patients with renal insufficiency.

[‖]Includes transurethral resection of bladder tumor and prostate, and any biopsy, resection, fulguration, foreign body removal, urethral dilation or urethrotomy, or ureteral instrumentation including catheterization or stent placement/removal.

[**]Clindamycin, or aminoglycoside + metronidazole or clindamycin, are general alternatives to penicillins and cephalosporins in patients with penicillin allergy, even when not specifically listed.

[††]Intestine: Common intestinal organisms include aerobes and anaerobes: *E. coli*, *Klebsiella* spp, *Enterobacter*, *Serratia* spp, *Proteus* spp, *Enterococcus*, and *Anaerobes*.

[‡‡]Skin: Common skin organisms are *S. aureus*, coagulase negative *Staphylococcus* spp, Group A *Streptococcus* spp.

[§§]For surgery involving the colorectum, bowel preparation with oral neomycin plus either erythromycin base or metronidazole are added to systemic agents.

[χ]Routine administration of vancomycin for AP is not recommended.[43] The antimicrobial spectrum of Vancomycin is less effective against methicillin-sensitive strains of *S. aureus*.

From Lightner DJ, Wymer K, Sanchez J, et al: *Urologic procedures and antimicrobial prophylaxis,* 2019 (website):
https://www.auanet.org/Documents/Guidelines/PDF/Antimicrobial%20Prophylaxis%20Table%20V.

AP is not without morbidity because drug reactions and allergic complications, although rare, may result in minor reactions such as rashes or gastric disturbances, or significant sequelae such as allergic nephritis, or anaphylaxis.

The new BPS on Urologic Procedures and Antimicrobial Prophylaxis includes some key updated recommendations, specifically regarding asymptomatic bacteriuria and funguria. Asymptomatic bacteriuria and asymptomatic funguria do not require treatment before a surgical procedure that does not violate the urothelium. The orthopedic literature has shown that there is no benefit to treating asymptomatic bacteriuria even in the setting of a total knee or hip prosthetic replacement (Sousa et al., 2014). The same is true of patients undergoing open heart surgeries (Soltanzadeh and Ebadi, 2013). Repeat urinalysis to demonstrate clearing of asymptomatic bacteriuria is also not recommended (Ramos et al., 2016).

The EAU infection guidelines published in 2017 concluded that before urologic surgery, in diagnostic and therapeutic procedures not entering the urinary tract, asymptomatic bacteriuria is not generally considered a risk factor, and screening and treatment are not considered necessary. However, the EAU guideline states that in procedures entering the urinary tract and breaching the mucosa, particularly in endoscopic urologic surgery, bacteriuria is a definite risk factor. In these patients, a urine culture must be taken before interventions and in case of asymptomatic bacteriuria, preoperative treatment is recommended (Bonkat et al., 2019). The EAU guideline also reports the treatment of asymptomatic bacteriuria is not recommended before arthroplasty surgery.

In addition, low-risk patients with asymptomatic bacteriuria and/or funguria may not require prophylaxis before a urologic surgical procedure that does not violate the urothelium with the exception of pregnant females. However, the statement does recommend single-dose antifungal prophylaxis for patients undergoing endoscopic, robotic, or open surgery on the urinary tract.

The IDSA 2016 clinical practice guidelines for management of candidiasis strongly recommended all patients with candiduria who are undergoing any urologic procedure be treated with either oral fluconazole or intravenous amphotericin B for several days before and after intervention (Pappas et al., 2016). The AUA BPS disagrees with this recommendation and states that antifungal prophylaxis should be used in patients undergoing specific endoscopic procedures in which high pressure irrigants are used (transurethral resection of bladder tumor [TURBT], transurethral resection of the prostate (TURP), ablative outlet procedures, therapeutic URS, and entry into urinary tract). Full antifungal treatment is recommended for patients with symptomatic fungal UTIs at the time of stent or drainage tube change. Neutropenic patients with funguria and a urinary tract obstruction require a longer course of periprocedural antifungal treatment. Those patients undergoing treatment of fungal balls (mycetoma) should have preoperative fungal cultures and periprocedural antifungal treatment for 5 to 7 days.

The panel recommended considering AP at the time of select procedures, including voiding trials, and catheter, drain, stent, or nephrostomy tube removals, particularly if other risk factors are present. A recent meta-analysis published in 2013 revealed a significantly lower prevalence of symptomatic UTIs with AP at the time of catheter removal in surgical and medical patients (Marschall et al., 2013).

The BPS specifically looked at the use of single-dose AP for each category of skin incision. The statement suggests that single-dose AP is not necessary in Class 1/Clean Procedures (uninfected, no GU or GI tract entry) except in groin or perineal incisions. The BPS recommends AP for those patients undergoing Class II/clean-contaminated GU procedures, which includes prostate biopsy. For transurethral procedures and therapeutic upper endoscopic procedures, single-dose AP (including first- or second-generation cephalosporins or trimethoprim/sulfamethoxazole) covering enterococci and gram-negative pathogens is recommended. For patients undergoing Class III/contaminated procedures, AP is strongly recommended because the risk of a surgical site infection (SSI) or systemic infection is high. The BPS recommends coverage of aerobic and anaerobic organisms for those undergoing colorectal surgical procedures (first-generation cephalosporin and metronidazole). The BPS does not discuss GU prosthetic antimicrobial coverage. However, it does comment that generally, AP that covers skin flora (coagulase-negative staphylococci and gram-negative bacilli) is recommended. Finally, class IV wounds are infected, and empirical antibiotics are initiated until final culture results are available.

Urethral Catheterization and Removal

The indications for the routine use of prophylactic antimicrobial agents before urethral catheterization vary and depend on the health, sex, and specific living circumstances of the individual patient, as well as the indication for catheterization (Schaeffer, 2006)**. The risk of infection after one-time urethral catheterization is 1% to 2% in healthy domiciliary women; however, this risk rises significantly in hospitalized patients** (Thiel and Spuhler, 1965; Turck et al., 1962). Thus, for patients with risk factors for infection (see Box 55.13), AP with an oral agent such as TMP-SMX should decrease the risk of postprocedural infection (see Table 55.15).

A recent Cochrane review published in 2013 looking at AP for short-term catheter (defined as ≤14 days) bladder drainage in adults found that surgical patients who received AP (3-day duration postop or from postop day 2 to catheter removal) had a reduced rate of bacteriuria and other signs of infection, including pyuria, fevers, and gram-negative urine cultures (Lusardi et al., 2013). Importantly, the authors did conclude that because of the limited evidence and allergic reactions or side effects from the AP, the results should be interpreted with caution. Patients who require long-term intermittent catheterization should not be on routine prophylaxis, because the rates of UTI are comparable and the overall risk of infection is low (Clarke et al., 2005; Duffy et al., 1995).

Prolonged use of an indwelling urethral catheter is common in hospitalized patients and is associated with an increased risk of bacterial colonization, with a 5% to 10% incidence of bacteriuria per catheter day for each day the catheter is in place (Saint and Lipsky, 1999; Sedor and Mulholland 1999; van der Wall et al., 1992). **Prophylactic administration of antimicrobial agents during**

catheterization is not generally recommended because bacterial resistance can develop rapidly and complicate subsequent necessary antimicrobial treatment (Clarke et al., 2005). This is supported by the Cochrane Database of Systematic Reviews that concluded that antimicrobials given postprocedurally until catheter removal or for the first 3 postoperative days did not reduce rates of bacteriuria or infection (Niël-weise and van den Broek, 2005).

The natural history of bacteriuria after catheter removal has not been comprehensively studied. Harding et al. (1991) reported that in asymptomatic bacteriuric women who had been catheterized for 4 to 6 days, 25% developed a UTI within 14 days of catheter removal. In this study, 1-day treatment with TMP-SMX was as effective as a 10-day course in resolving infections. Similar studies on the natural history of post-catheterization bacteriuria have not been performed in male patients.

Data from Polastri et al. (1990) suggest that AP for chronic indwelling catheter changes is not indicated. In their study of 46 catheter changes, bacteremia occurred 4% of the time and, when noted, was associated with very low concentrations of bacteria in the cultures. Systemic sequelae were not noted.

Urodynamics

Urodynamics (UDS), like cystoscopy, is a minimally traumatic procedure with limited urothelial injury that poses a small risk of local infection in hosts with normal anatomy and immune response. Several recent studies support this notion. According to the AUA Best Practice Policy on Urologic Surgery Antimicrobial Prophylaxis, prophylactic antibiotics are not indicated before UDS for patients without UTI risk factors ("index patients") (Wolf et al., 2008).

A large systematic review published in 2008 including 8 RCTs with 995 (mostly female) patients undergoing UDS compared prophylactic antibiotics with placebo or no treatment. The authors concluded there was a 40% reduction in the risk of bacteriuria and that 13 patients would need to be given prophylactic antibiotics to prevent one episode of bacteriuria (Latthe et al., 2008). This review did not assess the occurrence of symptomatic UTI, but it has been estimated that only 8% of women develop a symptomatic UTI within 1 week of a diagnosis of asymptomatic bacteriuria (Hooton et al., 2000). **In 2012 a Cochrane review evaluated the role of prophylactic antibiotics to reduce the risk of UTIs after UDS** (Foon et al., 2012). The review included 9 RCTs with 973 patients (76%

female). Patients receiving prophylaxis had fewer UTIs (20% vs. 28%), but there was no statistically significant difference. **The authors concluded there was not enough evidence that prophylaxis reduced symptomatic UTIs.**

In 2017 the Society of Urodynamics, Female Pelvic Medicine, and Urogenital Reconstruction (SUFU) published a Best Practice Policy Statement on UDS AP in the non-index patient (Cameron et al., 2017)**. The statement recommends that all patients be screened for symptoms of UTI and undergo dipstick urinalysis. If the provider suspects a UTI, the UDS should be postponed until the UTI has been treated. Patients undergoing UDS who do NOT require AP include those with no known GU anomalies, patients with diabetes, those with prior GU surgery or a history of prior UTI, postmenopausal women, recently hospitalized patients, and patients with cardiac valvular disease, nutritional deficiencies, or obesity. The panel does recommend periprocedural antibiotics in those patients with increased risk factors for UTI after UDS: relevant neurogenic LUT dysfunction, elevated postvoid residual, asymptomatic bacteriuria, immunosuppression (including renal transplant patients), age over 70, and an indwelling catheter, external collection device, or intermittent catheterization. The majority of these recommendations are based on Level IV (low level) evidence because of the lack of well-done studies. As always, clinical judgment of each individual scenario should supersede these recommendations, which, as stated, are not based on high-level evidence.** The authors strongly recommend careful and judicious use of AP until better evidence reveals the true need. Finally, the panel did recommend AP for patients undergoing UDS who have had an orthopedic total joint implant within the prior 2 years or who are considered at increased risk of developing joint infections from bacteremia (see Table 3 of Cameron et al. 2017, p 924). The first choice for prophylaxis is a single oral dose of TMP-SMX before UDS. Acceptable alternatives include first- and second-generation cephalosporins, amoxicillin/clavulanate, fluoroquinolones, and parenteral aminoglycoside plus ampicillin. The panel only found one study that used a 1-day AP course of nitrofurantoin in patients undergoing UDS and cystoscopy. They demonstrated no improvement in bacteriuria with nitrofurantoin AP (Cundiff et al., 1999). In light of the black box warning on quinolones and the lack of well-done studies, the authors currently use nitrofurantoin as an alternative to TMP-SMX.

Transrectal Ultrasound-Guided Prostate Biopsy

Infectious complications after prostate biopsy have increased in recent years, with reported rates from 0.1% to 7.0% and sepsis rates from 0.3% to 3.1% (Loeb et al., 2011; Nam et al., 2010)**. The most common cause for infection after transrectal prostate biopsy is fluoroquinolone-resistant *E. coli*** (Liss et al., 2015)**. The most common risk factor is exposure to antimicrobials within 6 months of the biopsy. The use of prophylactic antimicrobials for transrectal ultrasound-guided prostate biopsy (TRUS-Bx) reduces postprocedural fever and UTI in most studies.** The class and duration of antimicrobial treatment are more varied and controversial. AP with fluoroquinolones has been shown to significantly reduce the rate of infectious complications compared with placebo (8% vs. 25%) (Kapoor et al., 1998; Shandera et al., 1998; Sieber et al., 1997; Tal et al., 2003; Taylor and Bingham, 1997a,b; Zani et al., 2011).

However, **several recent studies have highlighted an increasing trend of infectious complications caused by fluoroquinolone-resistant organisms** among men undergoing TRUS-Bx (Binsaleh et al., 2004; Feliciano et al., 2008; Han et al., 2005; Lange et al., 2009; Ng and Chan, 2008; Young et al., 2009; Zaytoun et al., 2011). Prevalence rates for colonization with fluoroquinolone-resistant organisms in this patient population have been reported to be as high as 22% (Liss et al., 2011). Nevertheless, more than 90% of urologists continue to use fluoroquinolones empirically for AP before TRUS-Bx (Antsupova et al., 2014; Shandera et al., 1998). The increasing prevalence of infectious complications with fluoroquinolone-resistant bacteria in men undergoing TRUS-Bx suggests that this approach may not be judicious for some patients (Taylor et al., 2012). Indeed, of fluoroquinolone-resistant strains obtained (by rectal swabs) from men before prostate biopsy, 70% had an enhanced virulence profile (Liss et al., 2013).

Empirical augmented prophylaxis with a typical combination of aminoglycosides and fluoroquinolones has been effective in recent studies (Ho et al., 2009; Kehinde et al., 2013). A recent meta-analysis of 3 RCTs showed the superiority of augmented prophylaxis in reducing UTIs and hospitalizations after prostate biopsy (Yang et al., 2015); however, it is inevitable that bacterial resistance will evolve to challenge even these regimens.

Rectal swab culture obtained before TRUS-Bx allows for the isolation and identification of fluoroquinolone-resistant organisms from a patient's native

intestinal flora. Targeted prophylaxis has been extensively studied. A meta-analysis published in 2014 included 8 studies comparing targeted prophylaxis with empirical fluoroquinolone prophylaxis. The study reported that targeted prophylaxis was more efficacious in reducing infectious complications (Roberts et al., 2014). A more recent study by Liss et al. (2015) found no significant difference (between empirical and targeted prophylaxis) in sepsis rates in 5355 patients at Kaiser Permanente centers in the United States. In a study using targeted prophylaxis based on bacterial sensitivities of rectal swabs before TRUS-Bx, 19.6% of men had fluoroquinolone-resistant organisms. There were no infectious complications in the men who received targeted prophylaxis, whereas there were infectious complications, including sepsis, in 2.6% on empirical prophylaxis (Taylor et al., 2012). Cost-effectiveness analysis revealed that targeted prophylaxis yielded a cost savings of $4499 per post–TRUS-Bx infectious complication averted. Per estimation, 38 men would need to undergo rectal swab before TRUS-Bx to prevent 1 infectious complication. **Thus screening before TRUS-Bx and targeted prophylaxis should be considered as a thoughtful, predictable alternative to empirical prophylaxis. That being said, there are a number of issues related to the actual process of targeted prophylaxis including costs, time of extra visits, special culture media, and lab requirements.** There have been recent data to suggest that fosfomycin is as effective as fluoroquinolone in UTIs after TRUS-Bx (Noreikaite et al., 2018; Ongun et al., 2012; Roberts et al., 2018).

Recent studies suggest that a single-dose/day of fluoroquinolones is as effective as 3 days of treatment (Sabbagh et al., 2004). Together these data suggest that a minimum of 1 day of an antimicrobial agent is indicated for transrectal ultrasound-guided prostate biopsies**. In 2017 an Update of the AUA White Paper on the prevention and treatment of the more common complications related to prostate biopsy was published** (Liss et al., 2017)**. The authors made several key recommendations including preoperative assessment of risk factors for resistant bacteria, and urine culture and treatment of infections in men with lower urinary tract symptoms. The White Paper recommends fluoroquinolone AP within 1 hour of the prostate biopsy. If a rectal swab culture is done, culture-specific antibiotics should be administered (gentamicin and ceftriaxone are most common agents). Local antibiograms can help identify resistance patterns and the authors advocate alternative antibiotics if *E. coli* has more than 20% fluoroquinolone resistance. The EAU guideline recommends the use of AP in men before**

transrectal prostate biopsy as well as rectal cleansing with povidone-iodine in men before transrectal prostate biopsy.

Shock-Wave Lithotripsy

The AUA Guidelines on Surgical Management of Stones suggest that noninvasive procedures such as shock-wave lithotripsy do not require AP if the preoperative urine microscopy is benign (Assimos et al., 2016). A meta-analysis of nine RCTs examined the efficacy of AP for shock-wave lithotripsy and demonstrated no statistically significant benefit in reducing postoperative bacteriuria, fevers, or UTIs (Lu et al., 2012). In addition, a prospective study published in 2013 evaluating 526 shock-wave patients, of whom just 10 received AP, revealed very low rates of asymptomatic bacteriuria (0.8%) and UTI (0.2%) (Honey et al., 2013). **Prophylaxis for shock-wave lithotripsy is not recommended based on the low rates of bacteriuria and UTI; however, a history of a recent UTI or of infection stones should warrant a full treatment course of antimicrobial agents before shock-wave lithotripsy.**

Endoscopic Procedures: Lower Urinary Tract

Simple Cystoscopy (Without Manipulation)

Cystoscopy is a minimally traumatic procedure with limited urothelial injury performed on a diverse spectrum of patients, including young healthy women and older men. Several prospective trials (Burke et al., 2002; Clark and Higgs, 1990; Manson, 1988) of patients with preprocedure sterile urine report culture-proven rates of UTI between 2.2% and 7.8% after cystoscopy without AP. In Clark's report the risk of infection was higher in patients with a previous history of UTI. In a similarly designed study, Rane et al. (2001) reported a significantly higher postprocedure culture-proven infection rate of 21% without AP. Johnson et al. (2007) reported results of a randomized controlled trial of more than 2000 patients demonstrating reductions in bacteriuria with administration of single-dose trimethoprim or ciprofloxacin. In all the studies, single doses of antimicrobial agents reduced infections to between 1% and 5%. None of these studies had significant systemic infections reported after the cystoscopic procedures.

More recently, several studies have concluded that AP is not necessary before diagnostic cystoscopy. A retrospective review of more than 2000 patients who did not receive AP reported that only 1.9% of subjects developed a febrile UTI less than 30 days after a cystoscopy and all of the UTIs responded quickly to oral antibiotics; no patients required hospitalization for sepsis (Herr, 2014). This cohort included patients who had negative cultures before the cystoscopy (76%) as well as patients with asymptomatic bacteriuria (24%). A recent systematic review and meta-analysis published in 2015 showed no significant differences in post-cystoscopy UTIs when comparing patients who received AP with those who did not (Garcia-Perdomo et al., 2015). Arrabal-Polo et al. (2017) recently looked at the effect of AP in patients undergoing flexible cystoscopy and concluded that the use of ciprofloxacin or fosfomycin as prophylaxis does not appear to be indicated in flexible cystoscopy. Recent antibiotic use or hospitalization have been identified as risk factors that increase the likelihood of developing a UTI post-cystoscopy (Gregg JR et al., 2015). In a subsequent study these same investigators found that incorporating infection risks in conjunction with analysis of an antibiogram decreased the use of AP before cystoscopy without increasing the rate of post-procedure UTIs (Gregg et al., 2018).

Based on recent evidence, AP is not necessary for the overwhelming majority of diagnostic cystourethroscopy procedures. The EAU 2017 guideline on infections states “given the low absolute risk of post-procedural UTI in well-resourced countries, the high number of procedures being performed, and the high risk of contributing to increasing antimicrobial resistance the panel consensus was to strongly recommend not to use antibiotic prophylaxis in patients undergoing urethrocystocopy (flexible or rigid)” (Bonkat et al., 2019).

Transurethral Resection of the Prostate and Bladder (Cystourethroscopy With Manipulation)

Therapeutic transurethral lower urinary tract procedures increase the risk of localized infections compared with simple diagnostic cystoscopy. Although not delineated in any prospective studies, several risk factors likely increase infectious complications, including trauma to the mucosa, increased duration and/or degree of difficulty of the procedure, pressurized irrigants, and manipulation or resection of infected material. The most well-studied lower urinary tract procedure is **transurethral resection of the prostate (TURP).** In a meta-analysis of 32 studies comprising 4260 patients, a risk reduction was noted in bacteriuria from 26% to 9.1% on postoperative urine cultures obtained 2 to 5 days after the procedure for patients treated with prophylactic antimicrobial agents (Berry and Barratt, 2002). Similarly, septicemia (defined as rigors, persistently elevated temperature [>38.5°C], and an elevated C-reactive protein level) decreased from 4.4% to 0.7% with AP. The most effective antimicrobial classes included fluoroquinolones, aminoglycosides, cephalosporins, and TMP-SMX. **Single doses of antimicrobial agents did lower the relative risk of bacteriuria, but not as significantly as antimicrobial agents administered for short courses (2 to 5 days) while the urethral catheter remained in place.** Although continuation of antimicrobial therapy while the catheter is in place is not truly prophylaxis, continuation of the initial prophylactic antimicrobial agent for an anticipated short period of time (with catheter in place) does not increase the risk of developing antimicrobial-resistant organisms. In a randomized controlled trial of 243 patients undergoing transurethral resection of bladder tumors (TURBTs), three perioperative doses of cephadrine (compared with no antimicrobial) reduced the rate of bacteriuria (MacDermott et al., 1988). No recent trials have otherwise investigated prophylaxis for **TURBT;** however**, evidence from TURP procedures suggests that prophylaxis would reduce bacteriuria in these procedures. However, the EAU guidelines based on a systematic review of two RCTs found no benefit for AP in patients undergoing TURBT and recommends AP prophylaxis to reduce infectious complications in only high-risk patients undergoing transurethral resection of the bladder.**

Other cystoscopic procedures with manipulation (e.g., laser prostatectomy, bladder biopsies) have not been well studied. However, the similarity in terms of tissue trauma and invasiveness would suggest that the data regarding TURP and TURBT can be extrapolated. Nevertheless, a recent publication looked at the utility of preoperative antibiotics before bladder biopsy and showed that there was no difference in the rate of UTI or febrile UTI in those patients undergoing bladder biopsy in the office setting (without prophylaxis) versus the operating room (with prophylaxis) (Lipsky et al., 2017)**. This is a challenge as the current Center for Medicare and Medicaid Services (CMS) mandates require AP before cystoscopy and biopsy in the OR. IDSA and the AUA guidelines concur with the CMS mandate. The IDSA guidelines on surgical prophylaxis in urology recommend AP with a fluoroquinolone, trimethoprim-sulfamethoxazole, or cefazolin for lower tract instrumentation in patients with risk factors for infection. However, although CMS and the IDSA and AUA guidelines**

recommend AP before bladder biopsy, the recent study lends support to the notion that AP in all patients undergoing biopsy may not be necessary.

Patient risk factors associated with increased infectious risk include obesity, diabetes, smoking, immunosuppression, and malnutrition (Bratzler et al., 2013)**. In addition, the authors mention urologic-specific risk factors, including urinary tract anatomic anomalies, urinary obstruction, stones, and indwelling or externalized catheters. In 2009 Yokoyama et al. evaluated the possibility of discarding AP in patients undergoing TURBT. Their prospective study of 162 patients concluded that AP in patients undergoing TURBT did not provide benefit (symptomatic UTI rate of 3.4% in control group vs. 2.3% in the prophylaxis group, as well as no sepsis episodes in either)** (Yokoyama et al., 2009).

Patients who are known preoperatively to have UTIs should have the infections eradicated before the procedure is started; therefore, in these patients, preoperative antimicrobial agents are therapeutic and not prophylactic. Failure to eradicate bacteriuria results in bacteremia in 50% of patients (Morris et al., 1976).

Diagnostic and therapeutic upper tract studies that are performed with pressurized irrigants may induce urothelial injury. Prophylaxis with antimicrobial agents that cover uropathogens is indicated.

Endoscopic Procedures: Upper Urinary Tract

Ureteroscopy

Diagnostic and therapeutic upper tract endoscopic procedures have an increased risk of localized infections compared with simple diagnostic cystoscopy because of several factors, including increased trauma to the mucosa, increased duration and/or degree of difficulty of most ureteroscopic procedures, increased pressure of irrigants, and (when applicable) manipulation or resection of infected material. **The use of AP is supported** by a randomized trial involving 113 patients undergoing ureteroscopy in which prophylactic fluoroquinolone administration significantly reduced postprocedure bacteriuria (13% vs. 2%) in a healthy population of individuals with ureteral stones and uninfected preoperative urine (Knopf et al., 2003). If an infection or infectious material is suspected, culture and a full treatment course of an appropriate antimicrobial are recommended before the procedure. Some urologists advocate for medical diuresis with furosemide during the procedure.

A recent systematic review and meta-analysis looked at a total of 11 studies with more than 4500 patients undergoing ureteroscopic lithotripsy. Deng et al. (2018) found no significant difference in risk of postoperative febrile urinary tract infections between those patients with and those without AP. However, those patients receiving a single dose of preoperative antibiotics had a significantly lower risk of bacteriuria and pyuria (Deng et al., 2018). The authors concluded by recommending a single dose of oral preoperative AP for patients undergoing ureteroscopic lithotripsy.

Ureteral Stenting

AP should be administered at the time of stent removal. If the patient has significant risk factors, stent culture should be performed at this time to help direct potential antimicrobial treatment if infection occurs. The rates of colonization of the urine range from 0 to 29% without the use of AP (Kehinde et al., 2004; Lojanapiwat, 2006; Riedl et al., 1999). Rates of stent colonization in the same series were significantly higher, ranging from 42% to 70%. Dwell time of the stent was the most significant factor influencing stent colonization, and this was not reduced by prophylaxis. Urine culture correctly identified the colonizing organism (stent culture) in only 15% of the cases.

Percutaneous Renal Surgery (Prophylaxis Indicated in All Patients)

Percutaneous renal surgery is commonly performed for large renal stones, ureteropelvic junction obstruction, and transitional cell carcinoma surveillance. Pyrexia and bacteremia occur frequently and likely stem from a combination of renal parenchymal injury, pressurized irrigation, and, in some cases, manipulation of infectious stones. There are no RCTs confirming the need for prophylaxis, but several studies demonstrated a relationship between the risk of postoperative infectious complications (including bacteriuria and sepsis) and the duration of the procedure, and amount of irrigant used (Dogan et al., 2002). **If preoperative urine cultures are positive, treatment of the infection should occur before surgery. Conversely, if preoperative cultures are negative, AP covering common urinary pathogens should be instituted** (Wolf et al., 2008) (see Table 55.6).

Open, Laparoscopic, and Robotic Surgery

Open surgical procedures can be classified as clean, clean contaminated, contaminated, and dirty (Table 55.16). **AP is indicated for clean-contaminated and contaminated wounds, whereas antimicrobial treatment with an appropriate agent should be instituted for dirty-infected wounds.** No large studies have evaluated the risk of surgical site infections for different laparoscopic urologic procedures. However, data in the general surgery literature suggest that the laparoscopic approach lowers the risk of surgical site infections (Kluytmans, 1997). Clean surgeries in urology include radical nephrectomy if the urinary tract is not entered. **All urologic procedures in which the urinary tract is opened electively are considered clean-contaminated procedures (Class II), whereas entry into an infected urinary tract is considered a contaminated procedure (Class III)** and carries a higher rate of surgical site infection (Cruse, 1992). **Antimicrobial agents should be active against the most likely infecting organism, should be administered within 1 hour of the procedure, and discontinued 24 hours after,** because several studies have failed to demonstrate beneficial effects of long courses of prophylaxis (Conte et al., 1972; Goldmann et al., 1977).

TABLE 55.16

Wound Classifications

Class I/clean	Uninfected operative wound without entry into pulmonary, GI or GU systems	Inguinal and scrotal procedures for noninfectious indications, RPLND.
Class II/clean-contaminated	Entry into pulmonary, GI or GU under controlled conditions; no other contamination	Opening into urinary tract, as in nephrectomy, cystectomy, prostatectomy, endoscopic procedures.
Class III/contaminated	Infected stone procedures, use of bowel segments	PCNL on struvite stones, infected stones. TRUS prostate biopsy.
Class IV/dirty	Open trauma, abscesses	Debridement; implication that the offending organisms were present prior to the index procedure.
Prosthesis Implantation	IPP, AUS	Antibiotic prophylaxis should cover likely skin organisms; increasing resistance, MRSA colonization has led many surgeons to use vancomycin perioperatively.

AUS, Artificial genitourinary sphincter; *GI,* gastrointestinal; *GU,* genitourinary; *IPP,* implantable penile prosthesis; *MRSA,* methicillin-resistant *Staphylococcus aureus*; *PCNL,* percutaneous nephrolithotomy; *RPLND,* retroperitoneal lymph node dissection; *TRUS,* transrectal ultrasound guided.

Modified from Mangram, AJ, Horan, TC, Pearson, ML, et al: Guideline for prevention of surgical site infection. *Am J Infect Control* 27:97, 1999.

In the United States, first-generation cephalosporins are commonly used for prophylaxis of clean-contaminated procedures because they have low incidences of allergic reactions, long half-lives, and low cost. For patients with a β-lactam allergy, the 2004 National Surgical Infection Prevention Project (NSIPP) guidelines recommend either vancomycin or clindamycin. Prophylaxis for urinary reconstruction with intestine requires increased anaerobic coverage, so the use of first-generation cephalosporins and anaerobic coverage with metronidazole is recommended. When use of the colon or appendix is anticipated for urologic reconstruction, the 2004 NSIPP and WHO recommendations include orally administered antimicrobial bowel preparation (neomycin plus erythromycin or neomycin plus metronidazole) 18 to 24 hours before surgery, and parenteral cefotetan or cefoxitin 30 to 60 minutes before incision (Bratzler and Houck, 2004). Recommendations for patients with a β-lactam allergy include clindamycin plus gentamicin, aztreonam, or ciprofloxacin. Dirty wounds in urology include all abscesses and traumatic perforations of the GU tract. Treatment of a dirty wound should begin with broad coverage of anticipated organisms and intraoperative wound cultures. Subsequent therapy and treatment duration depends on the sensitivities of the cultured organism.

Skin Preparation for Surgery

Although AP plays an important role in minimizing the risk of a surgical site infection, additional considerations are important to lessen the risk of introducing pathogens into the operative site. Pre-hospital bathing, mechanical bowel prep, hair removal, and perioperative skin preparation play a role in preventing infections. See AUA BPS for more information.

Vaginal Surgery

RCTs have not been reported for vaginal urologic surgery, but there is a large body of evidence for vaginal hysterectomy. An old meta-analysis demonstrated a dramatic decrease in incidence of pelvic infections when AP was used (Duff and Park, 1980). Chang et al. (2005) reported the results of a RCT showing that a course of antimicrobials of less than 24 hours was as effective as a long course in patients undergoing laparoscopic assisted vaginal hysterectomy. The AUA AP BPS recommended AP for all vaginal procedures including midurethral sling (MUS) surgery in 2010 and again in 2019. This recommendation is based on expert opinion. Several studies have looked to see if AP is necessary in MUS surgery. One study looked at 174 patients undergoing MUS without AP. The lack of AP was not found to lead to any higher risk of infections, although there was no control arm in this study (Harmanli et al., 2012). An RCT with and without prophylactic antibiotics for MUS was ended early because of lower-than-predicted infectious complications in both groups (Harmanli et al., 2011). Shepherd et al. (2014) performed a decision analysis looking at the necessity of AP before MUS surgery for SUI and concluded that since infectious complications are rare, AP may not be necessary.

Special Considerations

Patients With Risk of Endocarditis

The risk of infectious endocarditis (IE) after urologic procedures is low. Previous guidelines from the American Heart Association (AHA) had recommended routine prophylaxis, but the current recommendation is that the use of prophylactic antibiotics solely to prevent IE is **not recommended** (Wilson et al., 2007). However, these guidelines do acknowledge that instrumentation of the GU tract may result in transient enterococcal bacteremia. Since 2007 the AHA recommends that AP during GU procedures is not an effective strategy for the sole prevention of IE (Wilson et al., 2007).

The latest American College of Cardiology (ACC)/AHA guidelines state that administration of antibiotics is not beneficial for patients undergoing urologic procedures (Nishimura et al., 2017)**. The guideline states that IE is more likely to result from random bacteremia than from a GU procedure and that prophylaxis may prevent a very small number of cases, if any. The AHA does not recommend antimicrobial treatment even for high-risk patients (prosthetic cardiac valves, previous infectious endocarditis, or cardiac transplant patients with valve disease) undergoing instrumentation of the GU tract.**

Regardless, the guidelines do state that for patients with certain concomitant conditions (prosthetic cardiac valve, previous IE, congenital heart disease, cardiac transplantation) and an active infection or

colonization who are to undergo GU tract manipulation, including elective cystoscopy, antibiotic therapy to sterilize the urine may be reasonable (Class IIb evidence). Amoxicillin or ampicillin is suggested as a first-line agent for enterococci, vancomycin for those who cannot tolerate ampicillin, or culture-directed agents when possible (Wilson et al., 2007).

Patients With Indwelling Orthopedic Hardware

In 2003 a joint commission of the AUA, American Academy of Orthopedic Surgeons (AAOS), and infectious disease specialists released an advisory statement on AP for urologic patients with total joint replacement. The commission did not advise AP for urologic patients with joint replacements, pins, plates, or screws that were at least 2 years old. However, if the prosthetic joint or implant was inserted within 2 years, prophylaxis was recommended with either an oral quinolone or 2 g of ampicillin intravenously and 1.5 mg/kg of gentamicin (vancomycin if ampicillin allergy) intravenously 30 to 60 minutes before the procedure. The AAOS's most recent statement in 2009 recommends that clinicians consider AP for all total joint replacements prior to any invasive procedure that may cause bacteremia. The impetus for this recommendation was the combination of the significant cost of treating infected joint replacements and the potential adverse outcomes. In addition, the recent AUA BPS statement from 2019 does recommend AP for the prevention of prosthetic hip or knee prostheses, particularly for urologic procedures at high risk of bacteremia, those patients within 2 years of joint replacement, and high-risk patient populations. Although the risk for infection with urologic procedures is weak, the panel recommended AP because of the potential of catastrophic harm with a joint infection (Table 55.17).

TABLE 55.17

Antimicrobial Regimens for Patients With Indwelling Orthopedic Hardware

PATIENT TYPE	ANTIMICROBIAL RECOMMENDATION
Total joint inserted >2 yr ago, pins, plates, screws + no host risk factors	Not recommended empirically
Total joint inserted <2 yr ago or aberrant host factor(s)	Oral quinolone or ampicillin, 2 g IV + gentamicin, 1.5 mg/kg IV, 30–60 min before procedure Substitute vancomycin, 1 g IV, over 1–2 h before procedure if ampicillin allergy

---

From American Urological Association and American Academy of Orthopaedic Surgeons: Antibiotic prophylaxis for urological patients with total joint replacements. *J Urol* 169:1796–1797, 2003.

Prophylaxis on the basis of potential seeding of a prosthetic joint should be instituted for procedures including stone manipulation, transmural incision of the urinary tract, upper tract endoscopic procedures, procedures involving bowel segments, and transrectal prostate biopsy. In addition, patients with recent prosthetic joints or compromised host factors and urinary diversions, indwelling stents or catheters, a recent history of urinary retention, or UTIs should receive AP before urinary tract procedures.

Key Points: Antimicrobial Prophylaxis for Common Urologic Procedures

- AP entails treatment with an antimicrobial agent before and for a limited time after a procedure to prevent local or systemic postprocedural infections.
- The type of procedure and competency of the host defenses determine the need for AP.
- Special considerations for AP include patients undergoing TRUS-Bx, those with a risk of endocarditis and bacteriuria, and patients with indwelling orthopedic hardware.

Acknowledgments

The authors thank Justin Matulay, MD, and Michael Lipsky, MD, for their assistance with the compilation of references and creation of a new flow sheet for management of rUTIs, and they also thank Jeffrey Newhouse, MD, for his expert review of radiologic information and for providing images for the chapter.

Inflammatory and Pain Conditions of the Male Genitourinary Tract

---

Prostatitis and Related Pain Conditions, Orchitis, and Epididymitis

Michel Pontari MD

Prostatitis

Historical Perspective

In a presentation to the 1929 American Urological Association held in Seattle, Dr. Franklin Farman of Los Angeles gave a brief history of prostatitis and proposed a classification. He noted that knowledge of the prostate dates back to mentions by Herophilus in 350 BCE, and that Nicola Massa, a Venetian physician living the 16th century, is accredited with discovering and describing the prostate. The first description of prostatitis dates to 1838 by Verdies. Treatment by prostate massage was described by Posner of Berlin in 1893. Before this therapy, diseases of the prostate were treated by “applications to the perineum in the form of counter-irritation, heat, cupping, leeches and the like.” He proposed a classification of prostatitis divided into two groups based on bacterial cause: the specific or gonorrheal type and the nonspecific or secondary focal type. The gonococcal was divided into three types: simple catarrhal or follicular prostatitis from acute infection and spread from the posterior urethra, true chronic parenchymous prostatitis from repeated infections, and a final category of atrophic or atonic prostatitis. This latter category, he asserted, also includes symptoms of premature ejaculation and impotency but has other causative factors, “a discussion of which involves the field of neuro and psycho-pathology.” The second category of prostatitis was thought to come about from hematologic seeding from other infections.

The clinical course of infectious prostatitis was changed significantly with the development of antibiotics (Nickel, 2000). Krieger and Weidner (2003) contend that the contemporary history of prostatitis began with a letter to the editor published in the *Journal of Urology* in 1978 by George Drach et al. (1978). This is described as the first scientific recommendations for a systematic classification of patients with symptoms of prostatitis. The diagnosis was based on the microscopic examination and quantitative cultures of segmented urogenital tract specimens described by Meares and Stamey (1968) and four categories presented: (1) acute bacterial prostatitis with acute infection, (2) chronic bacterial prostatitis with recurrent episodes of bacteriuria by the same organism, (3) chronic bacterial prostatitis in which patients had symptoms of prostatitis, negative cultures, and inflammatory cells, and (4) prostatodynia, with symptoms of prostatitis including “prostatic discomfort” but no recognizable infection or inflammation.

Current Classification of Prostatitis

The current classification of prostatitis was developed at consensus conferences in 1995 and 1998; the National Institutes of Health (NIH) classification was published in 1999 (Krieger et al., 1999).

NIH Classification

I. Acute bacterial prostatitis
II. Chronic bacterial prostatitis
IIIA. Chronic prostatitis/pelvic pain syndrome, inflammatory
IIIB. Chronic prostatitis/pelvic pain syndrome, noninflammatory
IV. Asymptomatic inflammatory prostatitis

Categories I and II are similar to the Drach classification (Drach et al., 1978). Bacterial prostatitis accounts for 5% to 10% of cases. The categories of nonbacterial prostatitis and prostatodynia were transformed into category III chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS). Category III is subdivided as category IIIA, inflammatory, with the presence of white blood cells in expressed prostatic secretions (EPS), post–prostate massage urine (VB3) or seminal plasma, or category IIIB, noninflammatory, without the inflammatory cells. This mirrors the distinction between nonbacterial prostatitis and prostatodynia. There have been no clinically significant differences demonstrated between these two subclasses.

The term *prostatitis* for category III may be confusing. Historically, the pain was thought to come from the prostate, from infection, or from inflammation. However, we now recognize that the prostate may not be the source of the pelvic pain in these men, and the term *chronic pelvic pain syndrome* was adopted to reflect this understanding. Although categorized as prostatitis, the pain of CP/CPPS may have nothing to do with inflammation or the prostate in some men. Type IV is asymptomatic inflammatory prostatitis and is diagnosed in men with no genitourinary pain complaints. Thus type IV is most commonly found in the evaluation of other genitourinary tract issues, such as in biopsy looking for prostate cancer or on semen analysis for evaluation for infertility.

The NIH definition of category III CP/CPPS as adopted by the Chronic

Prostatitis Research Network is that of symptoms of pain or discomfort in the pelvis for at least 3 of the previous 6 months (Schaeffer et al., 2002b). Several exclusion criteria are also included, such as demonstration of uropathogenic bacteria detected by standard microbiologic methods, urogenital cancer, prior radiation or chemotherapy, urethral stricture, or neurologic disease affecting the bladder (Schaeffer et al., 2002b). Similar inclusion and exclusion criteria are being used in the ongoing NIH study on the multidisciplinary approach to pelvic pain (MAPP) (Landis et al., 2014).

Histopathology

Histology

The term *prostatitis* can refer to the presence of inflammation on a histology examination of the prostate or is also used to describe clinical syndromes manifest by genitourinary discomfort or pain described in the NIH classification. The relationship is certainly not completely clear, and use of the terms can be confusing. The classification also contains category IV, which is prostatic inflammation, including prostate-specific specimens such as EPS, VB3, seminal plasma, and biopsies. Asymptomatic in this classification is the absence of pain. Histologic inflammation is commonly found in specimens resected for benign prostatic hyperplasia (BPH) (Nickel et al., 1999) and in biopsies done looking for prostate cancer. In a study by McNeal, prostatic inflammation was found in 44% of sampled adult prostates (McNeal, 1968). More contemporary series have found that more than 70% of men at autopsy to have chronic inflammation (Zlotta et al., 2014). Increased numbers of intraepithelial lymphocytes in areas of category IV prostatitis compared with areas of normal prostate suggest that it may be immune or autoimmune in origin (Dikov et al., 2015).

A classification system proposed by Nickel et al. recommended reporting inflammation in prostatitis by its anatomic location in the prostate, either glandular (within a duct/gland epithelium or lumen), periglandular (lies within stroma but centered around ducts and glands and approaches 50 µm or less), or stromal (in the stroma and >50 µm from a gland). Extent of inflammation is defined as focal (<10%), multifocal (10%–50%), or diffuse (> 50%). Grade is 1, or mild (individual inflammatory cells separated by distinct spaces, <100 cells); 2, or moderate (confluent sheets of cell with no tissue destruction or lymphoid follicles, 100–300 cells); and 3, or severe (confluent sheets of inflammatory cells with tissue destruction or nodule formation, 100–500 cells) (Nickel et al., 2001).

Fig. 56.1 shows a representative section illustrating the three locations of prostatic inflammation.

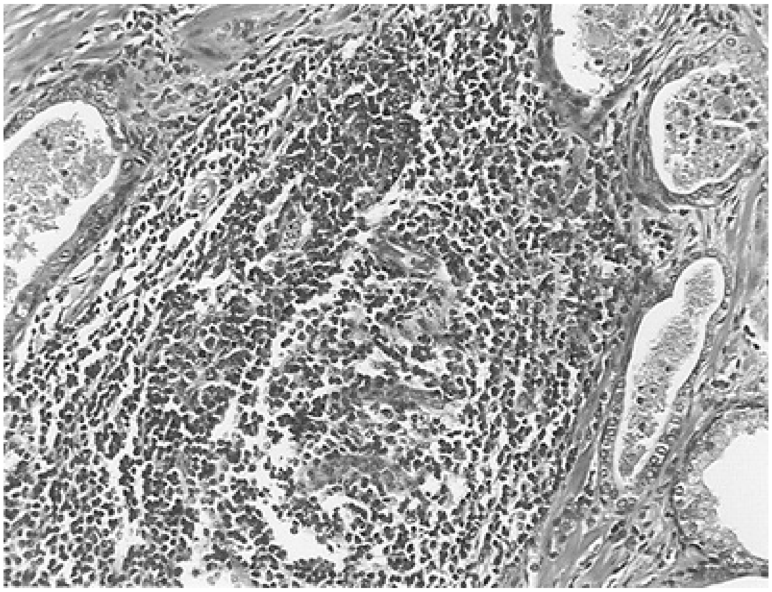

FIG. 56.1 Histologic preparation of a prostate specimen demonstrating areas of glandular, periglandular, and stromal inflammation (×400). (Courtesy Dr. Alexander Boag.)

Associated entities include corpora amylacea, which form from the deposition of prostatic secretions around sloughed epithelial cells; they do not usually cause inflammation unless they cause obstruction (Morales et al., 2005). Prostate calculi may contribute to inflammation by causing local obstruction or by providing a nidus for bacterial growth. The chemical composition of many stones suggest they may be caused by chronic infection (Dessombz et al., 2012). The presence of stones has been correlated to the symptoms of men with CP/CPPS (Shoskes et al., 2007). Occasionally they grow large enough to cause urethral obstruction and warrant surgical removal (Goyal et al., 2013).

Specific Cases of Prostatic Inflammation

Granulomatous Prostatitis

Granulomatous prostatitis is diagnosed by the histologic finding of epithelioid granulomas with or without other inflammatory cells (Uzoh et al., 2007). It is commonly found on specimens from transurethral resections and prostate biopsies. The most widely accepted grading system categorizes granulomatous prostatitis as specific, nonspecific, after transurethral resection of the prostate (TURP), and allergic granulomatous prostatitis (Epstein and Hutchins, 1984). It is commonly seen after intravesical Bacillus Calmette-Guerin (BCG) therapy for bladder cancer and can cause transient elevated levels of prostate-specific antigen (PSA) (Leibovici et al., 2000). Tuberculosis can also cause granulomatous prostatitis (Kulchavenya et al., 2012).

Immunoglobulin G Subclass 4 (IgG4)

Prostatitis has been described from IgG4-related disease (IgG4-RD). IgG4-RD is a recently described fibroinflammatory disease with multiorgan involvement. The first case of histologically confirmed IgG4 prostatitis was in 2006 (Yoshimura et al., 2006). IgG4-related disease is a fibroinflammatory condition characterized by several features: tendency to form tumorlike lesions at multiple sites, dense infiltrate of lymphocytes and IgG4 +plasma cells, characteristic pattern of fibrosis, and often, but not always, elevated levels of serum IgG4 (Deshpande et al., 2012). First described in autoimmune pancreatitis, multiple previously described disorders including Ormond disease (retroperitoneal fibrosis) are now considered to fall within this category (Stone et al., 2012). One of the characteristics of IgG4 disease is a dramatic response to corticosteroids. Patients with lower urinary tract symptoms from IgG4 disease have responded to corticosteroids with improvement in symptoms (Hart et al., 2013). There is as yet no characteristic presentation that would allow for identification of men with IgG4 prostatitis to allow for selection for treatment with steroids instead of surgery or standard BPH medications (Pontari, 2014). An obvious but perhaps small group is those men with concomitant autoimmune pancreatitis or sclerosing cholangitis and lower urinary tract symptoms (LUTS; Buijs et al., 2014). The diagnosis could be considered if histologic findings at the time of prostate biopsy for elevated PSA or a nodule suggest the diagnosis.

Category I Prostatitis: Acute Bacterial Prostatitis

Acute bacterial prostatitis (ABP) generally affects men age 20 to 40 years but also has a second peak of in cadence in men over the age of 60 (Krieger et al., 2011; Roberts et al., 1998). The causes of acute bacterial prostatitis are many. One is from ascending urethral infection. Characterization of virulence factors in the bacteria of men diagnosed with acute prostatitis indicated similar organisms in the urine specimens and rectal swab of the patient or sexual partner as the causative organism of the prostatitis in 6 of 9 men tested, indicating an ascending route of infection (Terai et al., 2000). Direct seeding from a prostate biopsy is a common cause. Other causes include intraprostatic reflux of infected urine that enters the ejaculatory and prostatic ducts of the posterior prostatic urethra and rarely spreads from the rectum via the lymphatic system. Hematogenous dissemination in the setting of bacterial sepsis or other blood-borne infections such as tuberculosis can occur (Brede and Shoskes, 2011).

Risk factors for the development of acute prostatitis include unprotected sexual intercourse, specifically insertive anal intercourse, phimosis, condom catheter use, indwelling urethral catheters, and urinary tract instrumentation, including endoscopic procedures and prostate biopsy (Dielubanza et al., 2014). Dysfunctional voiding and disorders causing urinary stasis, including distal urethral stricture and BPH, also put men at risk of developing prostatitis (Heyns, 2012). Acute prostatitis can occur after an episode of bacterial cystitis or epididymo-orchitis (Brede and Shoskes, 2011). A review of complications of clean intermittent catheterization showed that prostatitis occurs in up to 33% of these patients (Wyndaele, 2002).

The presentation of category I prostatitis is acute symptoms of a urinary tract infection (UTI), characteristically including urinary frequency and dysuria. Some patients have symptoms suggestive of systemic infection, such as malaise, fever, and myalgias (Krieger et al., 1999). Because of the UTI, pain can also be present in the lower abdomen and perineum. Urinary retention may be present because of acute swelling of the prostate, pain, or spasm of the bladder neck. In severe cases, patients can experience symptoms of sepsis: high fevers and chills, cardiovascular instability, and mental status changes (Brede and Shoskes, 2011). The presentation can vary by the cause of the prostatitis. As compared with spontaneous acute prostatitis as seen in younger men, patients who develop acute prostatitis after lower urinary tract manipulation or biopsy tend to be older and have a greater likelihood of septicemia (Kim et al., 2015; Millan-Rodriguez et al., 2006). Patients with Extended spectrum beta–lactamase (ESBL) positive bacteria also have significantly higher rates of septicemia (Kim et al., 2015). **Acute prostatitis should be considered in any man who presents with a febrile UTI. Febrile UTI in men can be from pyelonephritis, acute cystitis, or prostatitis. In a prospective study of 70 men with febrile UTI** (Ulleryd et al., 1999)**, more than 90% had increases in PSA and/or prostate volume**. In this cohort one-third had flank pain. This indicates that the prostate is likely involved even if the patient has signs of pyelonephritis.

Microbiology.

The most common causative organism is *Escherichia coli*, implicated in 65% to 80% of cases (Millan-Rodriguez et al., 2006). Other common gram-negative organisms include *Pseudomonas aeruginosa*, *Proteus mirabilis*, and *Klebsiella* and *Serratia* spp. (Etienne et al., 2008; Kim et al., 2014; Yoon et al., 2012). *Enterococcus* spp. account for up to 10% of cases of acute prostatitis (Kravchick et al., 2004; Schneider et al., 2003a). *Neisseria gonorrhoeae* should be considered as a possible cause in sexually active young men. Rare causes of bacterial prostatitis include obligate anaerobes and gram-positive bacteria other than *Enterococcus* spp. *Mycobacterium tuberculosis* is a rare cause of prostatitis and is usually associated with immunodeficiency. Prostate involvement is seen in approximately 10% of cases of genitourinary tuberculosis (TB). Common symptoms in these patients include perineal pain and dysuria (Kulchavenya, 2013; Kulchavenya et al., 2013). In tuberculous prostatitis, abscess cavities can form in the prostate, which can connect with sinuses to the perineum and result in fistula formation. In patients with impaired immunity such as HIV, other infecting organisms can cause prostatitis, including *Staphylococcus aureus*, *Klebsiella pneumonia*, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Salmonella typhi*, *M. tuberculosis*, and *Mycobacterium avium intracellulare* (Weinberger et al., 1988).

There are multiple virulence factors associated with the bacteria found in men with acute prostatitis. A contemporary study of previously healthy men aged 17 to 40 years old with acute prostatitis demonstrated 26 virulence genes from the cultured *E. coli* representing 5 virulence factors, including adhesins, toxins, and siderophores in addition to the expression of α-hemolysin, aerobactin, cytotoxic necrotizing factor-1 (CNF1), cytolethal distending toxin type 1 (CDT-1), and colicins. The isolates averaged 12.5 virulence genes (Krieger et al., 2011). URIs are uncommon in young healthy men, and this study demonstrates that bacterial virulence has a significant contribution to the development of acute prostatitis in this population (Krieger and Thumbikat, 2016). Another virulence factor that occurs in the bacteria causing acute prostatitis is the production of biofilms. Biofilms are a group of bacteria together in one area protected by a polysaccharide matrix. This makes the penetration of antibiotics more difficult. In a study of uropathogenic *E. coli* causing infection, biofilm formation was found more often in bacteria recovered from men with acute prostatitis (63%) as compared with cystitis (43%) and pyelonephritis (40%) (Soto et al., 2007), consistent with other studies (Kanamaru et al., 2006).

An important concept that has emerged is the difference in bacterial cause of prostatitis and antibiotic susceptibility depending on the cause. There are differences in organisms, depending on whether the acute prostatitis developed in the community or was nosocomial. A review indicated that community-acquired infections were three times more common than nosocomial infections. *E. coli* was the predominant organism, but nosocomial cases were more often caused by *P. aeruginosa*, enterococci, or *S. aureus* and had greater antimicrobial resistance and clinical failures (Etienne et al., 2008). Further distinctions are noted, depending on whether the acute prostatitis is spontaneous or occurs after lower urinary tract instrumentation or prostate biopsy. Patients with spontaneous acute prostatitis have predominantly *E. coli* (Millan-Rodriguez et al., 2006). Patients with acute prostatitis after manipulation also have predominantly *E. coli* but have a much higher prevalence of *Pseudomonas* spp. (20%) and have a higher risk of prostate abscess (Ha et al., 2008). Acute prostatitis after transrectal biopsy also has predominantly *E. coli*, but these bacteria are more resistant to fluoroquinolones (Kim et al., 2014), more likely to have ESBL-producing bacteria, and more likely to have positive blood cultures (Kim et al., 2015). **Thus the antibiotic selection for acute prostatitis must take into consideration the route of infection.**

Evaluation.

Patient history is important given the differences in the cause of the infection. The determination should be made if the patient has spontaneous acute prostatitis or has had lower urinary tract manipulation or a recent transrectal prostate biopsy. LUTS such as frequency urgency and dysuria are common. Associated signs of bacteremia and sepsis can be present, including fever, chills, and sweats (Brede and Shoskes, 2011). The history should assess for possible complicating factors such as diabetes, HIV, neurologic disease, and recent antibiotic use (Dielubanza et al., 2014). A palpable bladder may indicate urinary retention. **Acute prostatitis is the one situation in which one may palpate a truly "boggy" prostate from edema from inflammation. The prostate is tender and swollen in 60% to 90% of cases (**Etienne et al., 2008; Millan-Rodriguez et al., 2006**). Caution should be used to avoid aggressive palpation that could lead to bacterial dissemination and sepsis.**

Laboratory tests include a CBC, urinalysis, and midstream urine culture. Urine culture is positive in 60% to 85% of cases (Etienne et al., 2010). In a series of 347 patients with acute prostatitis, positive blood cultures were associated with a fever of more than 101.1°F, and although they generally grew organisms similar to the urine culture, contributed to the microbiologic diagnosis in 5% of cases (Etienne et al., 2010). Blood cultures should be drawn for patients with fever or chills before fever who have not yet received antibiotics. Prostate massage for prostate fluid should not be performed in the acute setting. Urinalysis can show white and red blood cells consistent with an infection. If the patient has a urethral discharge, urine can be sent for nuclear amplification tests for gonorrhea or chlamydia, but the prevalence of sexually transmitted infections in the setting of acute bacterial prostatitis is approximately 2% (Etienne et al., 2008). Renal function should be assessed to help guide antibiotic therapy. An assessment of postvoid residual urine should be made to rule out urinary retention, preferably noninvasively with an ultrasound. PSA testing is not recommended because the level is expected to be high during the acute phase (Game et al., 2003) and must be followed to ensure resolution back to normal levels. This may take up to 6 months to normalize and must be followed if elevated to make sure there is no elevation from an underlying prostate cancer (Zackrisson et al., 2003). Imaging studies are generally not indicated unless a prostate abscess is suspected. A transrectal ultrasound or CT scan can be used in this setting (Horcajada et al., 2003). There is no role for prostate biopsy for acute prostatitis.

Treatment.

It is important to fully treat acute prostatitis not only for the sake of the acute illness but also to prevent progression to a chronic infection as category II prostatitis (10.2%) or category III (9.6%) (Yoon et al., 2012). Infection with ESBL bacteria after a transrectal prostate biopsy is also a risk factor for progression to chronic prostatitis, reported as 25% of those with ESBL bacteria (Oh et al., 2013). Patients with systemic signs of infection need admission for IV antibiotics, hydration, and monitoring of laboratory studies. Some patients can be treated as an outpatient if they have no signs of systemic illness, can tolerate oral intake, and do not have urinary retention (Brede and Shoskes, 2011).

Antibiotics are the mainstay of therapy for acute bacterial prostatitis. The most recent European Association of Urology (EAU) guidelines on treating UTIs recommend the parenteral administration of high-dose bactericidal antibiotics such as a broad-spectrum penicillin, third-generation cephalosporin, or a fluoroquinolone. In initial therapy, any of these can be combined with an aminoglycoside (Grabe et al., 2015). One problem with this recommendation is the issue of men presenting with acute prostatitis after transrectal prostate biopsy. **Given the rates of resistance to quinolones and the incidence of ESBL bacteria seen in these cases, a strong argument can be made to use a carbapenem antibiotic in men presenting with fever and prostatitis after a transrectal prostate biopsy** (Dielubanza et al., 2014)**. This concern is reflected in the Update of the American Urological Association White Paper on the prevention and treatment of complications after prostate biopsy** (Liss et al., 2017)**, which states patients who have a fever after prostate biopsy should:**

- Not be offered fluoroquinolones or trimethoprim-sulfamethoxazole (TMP-SMX)
- Be managed with aggressive resuscitation and broad-spectrum antibiotic coverage: carbapenems, amikacin, or second- and third-generation cephalosporins (after urine and blood cultures)

Once the fever has subsided, or as initial treatment in patients who can be safely discharged, an oral fluoroquinolone, provided the bacteria is susceptible, is a good choice of therapy. Ciprofloxacin 500 mg twice daily or levofloxacin 500 mg daily can be used (Brede and Shoskes, 2011). It is recommended to reculture the urine after 1 week to make sure the bacteria has been cleared (Dielubanza et al., 2014). The traditional recommendation for antibiotic therapy for acute prostatitis to prevent chronic infection has been 4 weeks. However, 2 weeks of ciprofloxacin in men with a febrile UTI has been shown to produce a similar bacterial cure rate compared with 4 weeks of therapy (89% vs. 97%) and clinical cure rates at 1 year (72% vs. 82%). Thus 2 weeks is likely sufficient for duration of oral antibiotics (Ulleryd and Sandberg, 2003). Treatment for tuberculous prostatitis is with anti-TB chemotherapy for at least 6 months (Kulchavenya et al., 2016).

Adjuncts to Antibiotic Therapy.

The use of nonsteroidal anti-inflammatory medications can help with pain and inflammation. Patients may also benefit from the use of alpha-blockers if they have LUTS. For patients in urinary retention requiring drainage, traditional thinking has been to place a suprapubic catheter to avoid irritation of the prostate and possible bacteremia. For short-term care, straight catheterization or a brief period of urethral catheterization may be attempted (Brede and Shoskes, 2011).

Not every author agrees with this, however (Dielubanza et al., 2014), but for long-term bladder drainage, a suprapubic catheter is recommended.

Prostatic Abscess

Prostatic abscess should be suspected in men with high fever or a history of immunosuppression such as diabetes or HIV or who do not respond to initial therapy after 48 hours (Ha et al., 2008). Risk factors for development of abscess include history of prior catheter use, history of genitourinary surgery, increasing age and increased medical co-morbidities, indwelling catheter, instrumentation of the lower urinary tract, bladder outlet obstruction, acute and chronic bacterial prostatitis, chronic renal failure, hemodialysis, biopsy of the prostate, diabetes, cirrhosis, and HIV (Abdelmoteleb et al., 2017; Weinberger et al., 1988).

Imaging should be performed to look for a prostatic abscess. Methods recommended are transrectal ultrasound or CT scan. Ultrasound will show a hypoechoic area. CT offers the advantage of clarity of location and preoperative planning, as well as identification of any spread beyond the prostate (Vaccaro et al., 1986). Smaller lesions less than 1 to 2 cm may be treated conservatively with antibiotics (Abdelmoteleb et al., 2017). In a recent series, patients with an abscess smaller than 2 cm could be cured by medical therapy alone, but those who underwent surgical drainage required a shorter duration of antibiotic treatment than those treated conservatively (Lee et al., 2016). In men with progression of symptoms, treatment is indicated. Localized lesions, or those that are very peripheral, can be treated by percutaneous drainage under ultrasound guidance (Varkarakis et al., 2004). The recurrence rate after aspiration ranges from 15% to 33% (Ackerman et al., 2018). Lesions that do not respond to initial percutaneous drainage or lesions too large to adequately drain percutaneously should be taken for TURP to unroof the abscess (Fig. 56.2). A maneuver that has proven helpful is palpation and massage of the prostate after unroofing to help fully drain the abscess cavity. Rare cases of abscess that extend beyond the prostate may require open surgical treatment (Ludwig et al., 1999).

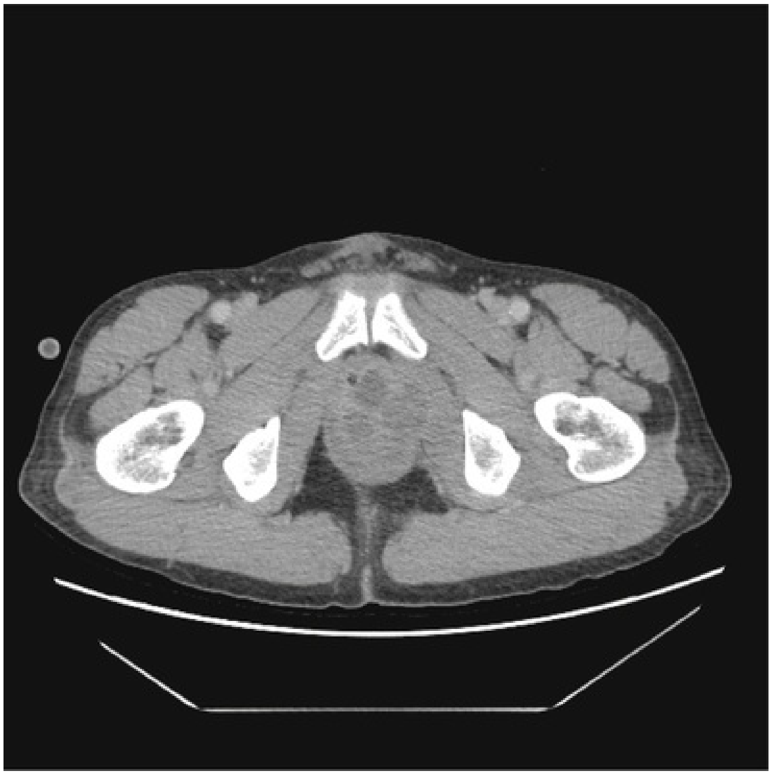

FIG. 56.2 Large prostate abscess in patient with dysuria and fever. Abscess was treated by transurethral unroofing.

Key Points

- Men with category I acute prostatitis experience acute symptoms of dysuria, frequency, and possibly fever.
- The most common causative organism is *E. coli*.
- Types of bacteria and antibiotic sensitivities differ by cause: spontaneous, after transurethral procedure, or after transrectal biopsy.
- Men with acute prostatitis after transrectal biopsy should be treated with carbapenems, amikacin, or second- and third-generation cephalosporins.
- A suprapubic tube should be used if long-term drainage is needed.
- Failure to respond to therapy should prompt imaging to look for a prostatic abscess.

Category II: Chronic Bacterial Prostatitis

Chronic bacterial prostatitis is characterized by recurrent urinary tract infections with the same organism (Krieger et al., 1999). This suggests a persistent prostatic source. This category accounts for 5% to 10% of cases of prostatitis (Krieger and Egan, 1991). **The symptoms of dysuria and pain generally respond to antibiotic treatment, and, unlike men with category III CP/CPPS, they are then relatively asymptomatic between episodes.**

Bacteria-Causing Category II Prostatitis.

Causative organisms for causing acute bacterial prostatitis, in most cases, are *E. coli, Pseudomonas, Proteus, Klebsiella*, and *Enterobacter* spp. (Gill and Shoskes, 2016). The role of enterococcus in causing chronic bacterial prostatitis is generally accepted. Of 6211 patients attending an Italian prostatitis clinic between 1997 and 2008, *Enterococcus faecalis* was found in 2745, or 44% (Cai et al., 2011). The significance of other gram-positive bacteria such as staphylococci and streptococci is debated. Microorganisms also considered to be of debatable significance include *Corynebacterium, Ureaplasma urealyticum*, and *Mycoplasma hominis*. Fastidious organisms that may require different culture techniques include *Mycoplasma tuberculosis* and *Candida* spp. (Schneider et al., 2003b). Similar to bacteria causing category I prostatitis, bacteria causing chronic bacterial prostatitis also are likely to form biofilms, which make them less likely to respond to treatment (Bartoletti et al., 2014).

Role of *Chlamydia* in Prostatitis?

The role of chlamydia as a cause of chronic bacterial prostatitis is still controversial. *Chlamydia* is an obligate intracellular gram-negative bacterium. It is surrounded by a rigid cell wall and needs other living cells to multiply because it cannot synthesize some essential nutrients (Mackern-Oberti et al., 2013). *Chlamydia* spp. can cause prostatic infection by an ascending route after urethral inoculation in animal models (Pal et al., 2004). The main argument is the difficulty of attributing the findings of *Chlamydia* spp. in the expressed prostatic secretions or semen to prostate infection alone given the possibility of urethral contamination, as *Chlamydia* spp. are a common cause of urethritis (Weidner et al., 2002). Studies of prostate tissue show *Chlamydia* spp. in 3% to 30%; however, the possibility of contamination from the prostatic urethra exists in tissue from TURP, transrectal biopsies, or open surgery and is eliminated only by perineal biopsy from the lateral lobes. Two studies of biopsies from the lateral lobes of the prostate have not detected *Chlamydia* spp. (Doble et al., 1989b;

Weidner et al., 1991b).

However, a growing body of literature on the possible role of *Chlamydia* spp. in prostate infection suggests some involvement. In a study looking for *Chlamydia* spp. in men with prostatitis compared with controls, *Chlamydia* spp. were identified by plasmid DNA found in the ejaculate of 35 of 78 patients but in none of 20 controls. Antichlamydial mucosal IgA was found in 69.2% of patients, with none found in the controls. The IgA levels correlated with symptoms and levels of IL-8 (Mazzoli et al., 2007). The presence of *Chlamydia* spp. has been linked to premature ejaculation (PE). In men with chronic prostatitis attributed to *Chlamydia* spp., 118 of 317 had PE (37.2%) as compared with 73 of 639 (11.5%) men with chronic prostatitis from common uropathogenic bacteria ($P < 0.0002$) (Cai et al., 2014). More compelling evidence was the report of a reduction in serum PSA in men with EPS or VB3 positive for *Chlamydia* spp. but negative VB1 treated with 4 weeks of a combination of levofloxacin and azithromycin; the resultant eradication of *Chlamydia* spp. and PSA response was also accompanied by a decrease in symptoms. This strongly suggests prostate involvement. Despite ongoing concerns (Benelli et al., 2017), some evidence supports a causative role for *Chlamydia* spp. in chronic bacterial prostatitis.

Diagnosis and Evaluation.

The diagnosis is currently made by the pre-massage and post-massage test (or two-glass test). The VB3 specimen gives information as to a persistent prostatic source of bacteria. The patient provides a midstream pre-massage urine specimen and a urine specimen (initial 10 mL) after prostatic massage to obtain expressed prostatic secretions (EPS) (Nickel et al., 2006). These specimens are then sent for culture. The previous method was the “four-glass test” as described by Meares and Stamey, which includes the first voided urine looking for urethral bacteria (VB1), the midstream urine (VB2), post-massage urine for EPS (VB3), and collection of the prostate fluid itself for culture (Meares and Stamey, 1968). The two-glass pre-massage and post-massage test is a simpler method and yields similar results. A study from the NIH Chronic Prostatitis Collaborative Research Network (CPCRN) examined a cohort of 353 men with CP/CPPS with complete four-glass data and noted that the two-glass test predicted a positive four-glass result with clinically acceptable accuracy (more than 95% of men would have had the same diagnosis if the four-glass test were performed) (Nickel et al., 2006). In men with human immunodeficiency virus (HIV), cultures should be sent not only for the usual bacteria but also for more atypical organisms, including anaerobes, anaerobes, fungi, and TB (Heyns and Fisher, 2005). There are no recommended diagnostic cutoff points for bacterial counts between the two specimens obtained, but some clinics use a 10-fold increase in the post-massage urine as being diagnostic of CP II (Benelli et al., 2017). Semen cultures are not recommended because of limited detection of causative bacteria (Weidner and Anderson, 2008) and decreased specificity resulting from skin contamination (Gill and Shoskes, 2016).

Urine should be assessed for hematuria. If present in the setting of infection, it should be rechecked 4 to 6 weeks after resolution of infection to look for resolution of the hematuria. Persistent hematuria should prompt an evaluation. Physical examination should evaluate for fever. Abdominal examination is necessary to rule out other causes of abdominal/suprapubic pain. Scrotal examination is needed to evaluate for any associated areas of inflammation and possible infection such as the epididymis and testis. A digital rectal examination is indicated to look for prostate size and any abnormalities to suggest prostate cancer. It is important to assess for bladder outlet obstruction and urinary retention. Retention of urine may predispose to recurrent urinary tract infection. A postvoid residual urine of more than 180 mL has been correlated with increased risk of infection (Truzzi et al., 2008). Urinary retention also increases the pathogenicity of bacteria (Johnson et al., 1993).

Not all patients with chronic bacterial prostatitis need imaging. In men younger than 45 years old with a first event of acute UTI, imaging showed no abnormalities. It is recommended, however, in this group to rule out urethral stricture. Men with a flow rate of more than 15 mL/min should be further evaluated (Abarbanel et al., 2003). Urethral strictures can occur with a UTI in up to 41% of cases (Santucci et al., 2007). Imaging is recommended for men with a UTI and history of diabetes, chronic kidney disease, stones, voiding difficulties, neurologic disease, poor response to antibiotics, infection with urea-splitting bacteria, or hematuria more than 1 month after the infection (Heyns, 2012).

Treatment of Chronic Bacterial Prostatitis (Category II).

The treatment of category II prostatitis is limited to antibiotics that can penetrate the prostate and achieve therapeutic levels. The prostate capillary bed lacks active transport mechanisms for antibiotics (Stamey et al., 1970). Penetration into the prostate, therefore, is dependent on passive transport, and the factors that influence this transport are drug concentration, lipid solubility, degree of ionization or charge, degree of protein binding, and size and shape of the molecule (Wagenlehner et al., 2013). Quinolones have excellent prostate penetration because of their configuration, including positively and negatively charged groups, also called a zwitterion. The fluid of chronic bacterial prostatitis is alkaline and contributes to concentration of the quinolones (Wagenlehner et al., 2005). These molecules also have high lipid solubility (Perletti et al., 2009). Other antimicrobial agents that have good to excellent penetration into prostatic fluid and tissue include tetracyclines because of their lipid solubility, macrolides because of their pKa values, and trimethoprim, which is a lipid-soluble base with a favorable pKa (Charalabopoulos et al., 2003b).

There are no American Urological Association (AUA) guidelines for antibiotic treatment of chronic bacterial prostatitis/category II, but the EAU has guidelines for this condition (Grabe et al., 2015). Fluoroquinolones such as ciprofloxacin and levofloxacin are the antibiotics of choice not only because of their tissue penetration but also because of their spectrum of coverage, which includes gram-negatives, including *Pseudomonas*, gram-positives, and atypical pathogens such as *Chlamydia* spp. and genital *Mycoplasma* spp. Duration of treatment is based on expert opinion; the recommendation is 4 to 6 weeks. This is in agreement with recent guidelines published by the Prostatitis Expert Reference Group from the UK (Rees et al., 2015b). Because of their ability to penetrate biofilms, the addition of a macrolide may be beneficial. In a trial by Magri et al., the combination of azithromycin 500 mg three times per week added to ciprofloxacin 750 mg per day for 4 weeks increased bacterial eradication rates compared with azithromycin and ciprofloxacin at the more standard regimen of 500 mg per day for 6 weeks (Magri et al., 2011).

Overall it is estimated that 60% to 80% of patients with *E. coli* and other gram-negative Enterobacteriaceae can be cured by the quinolone regimen (Wagenlehner et al., 2013). This is in comparison with only 30% to 50% with a 12-week course of Bactrim (timethoprim-sulfamethoxazole [TMP-SMX]) (Kurzer and Kaplan, 2002). However, in cases in which the bacteria are resistant to fluoroquinolones but susceptible to TMP-SMX, a 3-month course of TMP-SMX can be given. There are no evidence-based recommendations for treatment if the bacteria are resistant to both agents. A 2013 Cochrane review examined the treatment of chronic prostatitis (Perletti et al., 2013). For traditional bacterial prostatitis, there was no difference among the oral fluoroquinolones. No conclusion could be drawn regarding the optimal treatment duration; treatment ranged from 4 to 12 weeks. For chlamydial prostatitis, azithromycin was superior to Cipro and equivalent to clarithromycin.

CP II in HIV/Immunocompromised Patients.

In men with HIV, consideration should be made for low antimicrobial suppression for some time to reduce the risk of recurrence (Santillo and Lowe, 2006). In patients who are already treated with highly active antiretroviral therapy (HAART) and are still persistently immunocompromised, lifetime suppressive antimicrobials have been recommended to risk progression to prostatic abscess (Lee et al., 2001).

Beyond Quinolones.

In the setting of increasing quinolone resistance and trimethoprim resistance, other alternatives are needed. Alternatives that have data for use in chronic bacterial prostatitis include netilmicin, an aminoglycoside (no longer available in the US; Magri et al., 2016) and cefoxitin (Demonchy et al., 2018). Piperacillin-tazobactam achieves prostatic levels that would be adequate to treat infections from *E. coli*, *Klebsiella*, and *Proteus* but not adequate levels to treat *Pseudomonas* (Kobayashi et al., 2015). Fosfomycin has in vitro activity against *E. coli* with antimicrobial resistance, including ESBL strains (Karlowsky et al., 2014). It also has good penetration into the prostate (Gardiner et al., 2014). A dosage of 3 g every 48 to 72 hours was used in 15 patients with bacterial eradication in 8 and clinical cure in 7 (Los-Arcos et al., 2015).

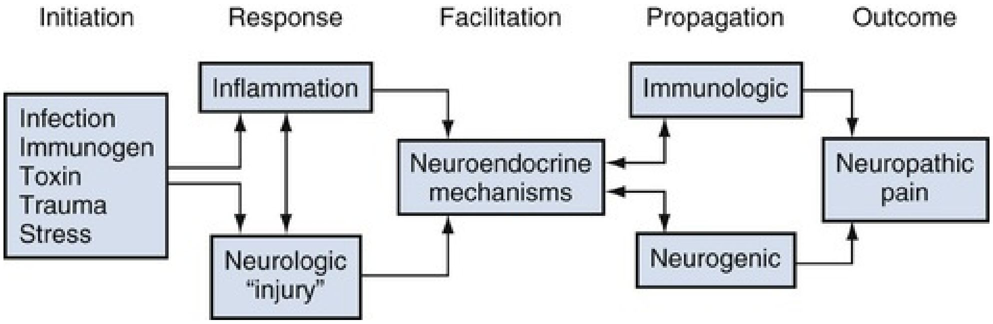
Adjunct treatments for refractory chronic bacterial prostatitis include alternate regimens of antibiotics and surgery. When antibiotic therapy fails to eradicate infection, the patient can be started on a daily dose of an antibiotic targeting an identified bacterial isolate. Duration is approximately 6 months, after which it should to be titrated down to maintain the lowest dose that results in symptom relief (Dielubanza et al., 2014). A trial of the medicine near 6 months may also be advisable to see if the antibiotic is still necessary. In self-start therapies, men send urine cultures when they have a recurrence of symptoms and start the antimicrobials at the start of symptoms (Dielubanza et al., 2014). For patients whose symptoms are refractory to medical therapy, TURP has been used with results of 52% to 67% of patients responding to TURP down to the surgical capsule (Barnes et al., 1982; Decaestecker and Oosterlinck, 2015).

Key Points

- Chronic bacterial prostatitis is characterized by recurrent urinary tract infections with the same organism.
- Unlike men with category III prostatitis/chronic pelvic pain syndrome, men with category II are relatively asymptomatic between episodes.
- Urinary retention as a cause of recurrent UTI must be ruled out.
- Men younger than 45 years old do not need imaging but need assessment for a urethral stricture.
- Treatment is with antibiotics that achieve adequate prostate concentrations.
- For refractory cases daily suppressive antibiotics or TURP can be used.

Etiology

Despite a concerted research effort in the past 20 years, the cause and much of the pathogenesis of CP/CPPS remain unknown. However, there is evidence to support a possible role for infection, neurologic causes, and inflammatory/autoimmune, endocrine, and psychological factors. It is likely the interplay between all of these that contributes to the creation and continuation of pelvic pain (Pontari, 2013). One hypothesis is that an insult such as infection, stress, or trauma in a genetically susceptible individual leads to neurogenic inflammation, which is maintained by these other factors (Fig. 56.3).



Initiation
Response
Facilitation
Propagation
Outcome
Infection
Immunogen
Toxin
Trauma
Stress
Inflammation
Neurologic "injury"
Neuroendocrine mechanisms
Immunologic
Neurogenic
Neuropathic pain

FIG. 56.3 Proposed cascade of initiation of chronic prostatitis and chronic pelvic pain syndrome (CPPS). Initial insult such as infection, immune response, toxin, trauma, or stress in genetically susceptible host leads to neurogenic inflammatory response. This is then facilitated and propagated by psychological, immune, neurologic, and endocrine mechanisms to produce the final outcome of the phenotype of CPPS.

Infection

The symptoms of CP/CPPS are similar to that of a true prostatic infection. Therefore infection has been commonly assumed by patients and clinicians to be the cause of the symptoms. A history of prior sexually transmitted disease (STD) increases the odds of prostatitis by 1.8 times (Collins et al., 2002). Although a history of STD seems to lead to greater risk of CP/CPPS, there is no evidence of an active STD in these men (Weidner et al., 1991a). There is no difference in the routine cultures of men with CP/CPPS and asymptomatic controls from urine, prostatic fluid, and post-prostate massage urine or seminal plasma (Nickel et al., 2003). Eight percent of men had uropathogenic bacteria, and roughly 70% had some form of bacteria in each group. This indicates that some asymptomatic men appear to routinely have bacteria in the prostate but may not by themselves produce disease or symptoms.

Molecular techniques that can identify bacteria without culture include polymerase chain reaction, which has failed to show a clear organism emerging as the source of CP/CPPS (Badalyan, 2003; Hochreiter et al., 2000; Krieger et al., 2000; Leskinen et al., 2003; Riley et al., 1998; Shoskes and Shahed, 2000; Takahashi et al., 2003; Xiao et al., 2013). A newer technique involves using a specific set of primers that amplifies bacterial DNA, and then algorithms can match the resultant sequences to specific organisms. This technique can identify all bacterial species present at more than 1% to 3% of the biome (Ecker et al., 2008). Using this technique, Nickel et al. reported the only significant difference was found in the initial stream (VB1) samples, with the organism *Burkholderia cenocepacia* overrepresented in the CP/CPPS patients ($P = 0.002$) compared with controls (Nickel et al., 2015). This organism is an opportunistic pathogen in patients with cystic fibrosis and is known to be able to form biofilms (Fazli et al., 2014; Ganesan and Sajjan, 2011). Organisms of this genus have been described in acute prostatitis (Arzola et al., 2007). In an animal model, a strain of bacteria called CP1, isolated from a man with CP/CPPS, induced and sustained chronic pelvic pain that persisted after bacterial clearance from the genitourinary tract (Rudick et al., 2011). Thus possibly certain bacteria produce pelvic pain. Recent studies also have found alterations in the microbiome of men with CP/CPPS compared with controls. Men with CP/CPPS have increased diversity of bacteria in the urinary tract at the phylogenic level that exhibit more varied clustering than men without symptoms (Shoskes et al., 2016). A parallel study showed less diversity in the gut microbiome in the CP/CPPS patients compared with controls (Shoskes et al., 2016).

Inflammation

The term *prostatitis* implies inflammation of the prostate gland. However only about one-third of men with clinical CPPS have been found to have prostatic inflammation on biopsy (True et al., 1999). **In those with inflammation in VB3, EPS, or seminal plasma, the degree of inflammation does not correlate with symptoms** (Schaeffer et al., 2002a). Data looking at individual cytokines vary widely and are not conclusive. The possibility of an autoimmune response in some men is supported by reports that some men with CP/CPPS have an increased lymphoproliferative response to prostate antigens (Motrich et al., 2007) compared with controls. These include a region of the prostatic acid phosphatase molecule, PSA (Kouiavskaia et al., 2009), and human seminal vesicle secretory protein 2 (SVS2) (Hou et al., 2012). Levels of the chemokines monocyte chemoattractant protein-1 and macrophage inflammatory protein-1-α are significantly elevated in patients with CP/CPPS compared with those without urologic disease or BPH, and elevated MIP-1-α levels showed positive correlation with not only absolute NIH-CPSI scores, but with pain components of the NIH-CPSI as well (Desireddi et al., 2008). Levels of IL-17 are elevated in men with CP/CPPS and correlate with patient symptoms (Murphy et al., 2015).

Neurologic Causes

The cardinal symptom in CP/CPPS is pain, which is mediated through the nervous system. In addition to the increased self-report of neurologic disease in men with CP/CPPS compared with controls (Pontari et al., 2005), there is evidence for differences in the autonomic nerve function of men with CP/CPPS. **There is evidence for central sensitization in the afferent and efferent nervous system in men with CP/CPPS** (Yang et al., 2003; Yilmaz U et al., 2007). Central sensitization is characterized by continued nerve activity in the absence of stimulation or which requires a very low level of nociceptive stimulation to continue (Woolf, 1983). There are no differences in sensory perception thresholds in these patients, indicating that there is no peripheral neuropathy (Yilmaz et al., 2010). Changes in brain structure and function have been seen on neuroimaging. Farmer et al. (2011) studied spontaneous pelvic pain, with men lying in the fMRI scanner for 10 minutes and rating their fluctuations in brain activity in the absence of any external stimulus. Pain perception was localized to the anterior insula and correlated with the intensity of self-reported pain (Fig. 56.4). There were also differences in the relationship of gray and white matter in men with CPPS compared with controls (Farmer et al., 2011). The findings in men with CPPS differ from those in other pain conditions, including low back pain (Baliki et al., 2011). Other imaging studies have indicated UCCPS patients have lower white matter tract density in areas of perception, integration of sensory information and pain modulation (Woodworth et al., 2015). Men with CP/CPPS have decreased connectivity between motor areas involved in pelvic floor control and the right posterior insula, an area involved in pain processing and sympathetic autonomic control. The greater pain was associated with less connectivity between the areas (Kutch et al., 2015).

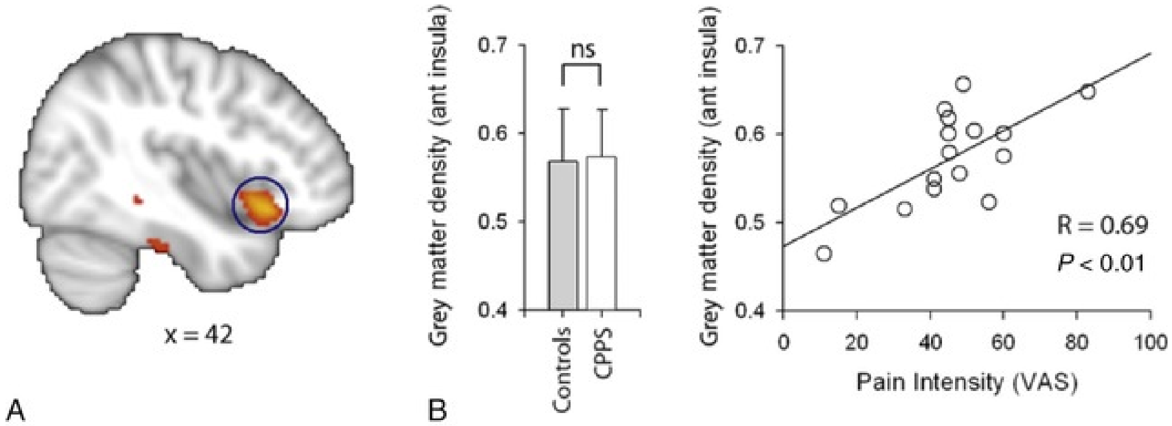


FIG. 56.4 Anterior insula activity is related to chronic prostatitis and chronic pelvic pain syndrome (CP/CPPS) pain intensity. (A) Peak activity from anterior insula *(blue circle)* identified from pain. The visual contrast shows significantly larger activity in pain task versus visual task *(bar graph),* and shows significant positive relationship between activity and CP/CPPS pain intensity (each symbol is individual subject in scatterplot). (B) Correlation of peak activity from anterior insula with clinical parameters of CP/CPPS. In addition to spontaneous pain intensity MPQ exhibited significant correlation with insular activity. (From Farmer MA: Brain functional and anatomical changes in chronic prostatitis/chronic pelvic pain syndrome. *J Urol.* 186[1]:117–124, Fig 3.)

Pelvic Floor Dysfunction

Neurologic abnormalities are postulated to also cause spasm in the pelvic floor. Patients with CP/CPPS have pathological tenderness of the striated pelvic floor muscle and poor to absent function in ability to relax the pelvic floor efficiently with a single or repetitive effort (Zermann et al., 1999). An electromyogram (EMG) study of the pelvic floor in these patients showed that compared with controls, men with CP/CPPS had (1) greater preliminary resting hypertonicity and instability and (2) lowered voluntary endurance contraction amplitude (Hetrick et al., 2006). A study by the CPCRN found that on physical examination, 14% of patients with CP/CPPS had tenderness of the internal pelvic floor, 13% had external pelvic floor tenderness, and neither was found in controls (Shoskes et al., 2008). On transabdominal ultrasound measurement of pelvic floor muscle mobility, compared with controls, men with CPPS have on average lower pelvic floor mobility resulting from increased tension (Khorasani et al., 2012).

Psychosocial Factors

Greater perceived stress is associated with greater pain intensity ($P = 0.03$) and disability ($P = 0.003$) in men with CP/CPPS (Ullrich et al., 2005). **Helplessness and catastrophizing predict overall pain along with urinary symptoms and depression** (Tripp et al., 2006). This was confirmed by a systematic review of 69 research articles looking at psychosocial influences (Riegel et al., 2014) that found an association of pain intensity with catastrophizing, perceived stress, and low satisfaction with relationships including sexual functioning. In the Boston Area Community Health (BACH) Survey, men who reported experiencing sexual, emotional, or physical abuse were at increased risk for symptoms of CP/CPPS (OR 1.7–3.3; Hu et al., 2007).

Endocrine Abnormalities

One of the common findings in chronic pain conditions is alterations of the hypothalamic-pituitary-adrenal axis; similar findings have been reported in CP/CPPS. On awakening, serum cortisol levels rise; there is a significantly greater cortisol rise in men with CPPS compared with controls. **Men with CPPS also have a lower baseline adrenocorticotropic hormone (ACTH) level and blunted ACTH rise in response to stress than men without symptoms** (Anderson et al., 2008).

Genetics

A twin study from the University of Washington compared self-reported lifetime physician diagnosis of CP/CPPS with so-called chronic overlapping pain conditions (COPC), including fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome (IBS), temporomandibular disorder, tension headaches, and migraine headaches. Compared with their non-CP/CPPS twin, those with CP/CPPS were 6 to 30 times more likely to report a COPC. The conclusion is that familial factors, either shared environmental factors or genetic factors, play a large role in the relationship between CP/CPPS and COPC (Gasperi et al., 2017).

Biomarkers

There have been few biomarkers that correlate with symptoms in CP/CPPS. One of these markers is nerve growth factor (NGF), a neuropeptide that plays a role in nociception (Miller et al., 2002). NGF is reported to also decrease in men with CPPS who respond to treatment but not in those who do not respond (Watanabe et al., 2011). In the MAPP study, in men with UCCPS, pain severity was significantly positively associated with concentrations of matrix metallopeptidase 9 (MMP-9) and MMP-9/NGAL (neutrophil gelatinase-associated lipocalin) complex, and urinary severity was significantly positively associated with MMP-9, MMP-9/NGAL complex, and VEGF-R1 (vascular endothelial growth factor receptor 1) (Dagher et al., 2017). VEGF and MMP-9 are known to play a role in neuropathic pain (Ji et al., 2009; Selvaraj et al., 2015), although MMP/NGAL may be a marker of infection or inflammation (Chen et al., 2007).

Abnormal Sensory Processing

One of the hallmarks of patients with centralized chronic pain is generalized or global abnormality of sensory processing (Jensen et al., 2009; Kosek et al., 1996). In the MAPP study, this was tested using quantitative sensory testing (QST), in which a quantifiable pain stimulus, a computer-controlled pressure stimulus, is applied to the thumbnail. Patients with UCCPS (49% male) had significantly increased pain sensitivity compared with healthy controls (41% males). However, they were less sensitive to a mixed pain comparison group of patients with fibromyalgia, chronic fatigue syndrome, and irritable bowel syndrome (Clemens et al., 2018).

Key Points

- Men with CP/CPPS have amounts of bacteria in urine, prostate fluid, and seminal plasma equal to that in men without pain.

- There is evidence of central sensitization of the central nervous system (CNS) in afferent and efferent nerves.
- In those with inflammation in VB3, EPS, or seminal plasma, the degree of inflammation does not correlate with symptoms.
- Helplessness and catastrophizing predict overall pain along with urinary symptoms and depression.
- Men with CPPS also have a lower baseline ACTH level and blunted ACTH rise in response to stress than men without symptoms.
- Men with CP/CPPS have increased pain sensitivity compared with controls.

Symptoms in Chronic Prostatitis and Chronic Pelvic Pain Syndrome

The symptom that distinguishes category III prostatitis CP/CPPS from other conditions such as BPH is pain. One of the early attempts to catalog the symptoms of CP/CPPS was an Internet survey by Alexander and Tressel that surveyed of 163 men with prostatitis and reported that the most frequently reported and most severe symptom was pain in the pelvic region, followed by urinary frequency and obstructive voiding symptoms. The most frequent site of pain was the perineum (Alexander and Trissel, 1996).

In 1999 the NIH set out to develop a symptom score that could be used as an outcome measure for clinical trials (Litwin et al., 1999). It also has proved useful to help categorize the symptoms of CPPS. The development included focus groups of patients judged to have CP/CPPS, generally pelvic pain in the absence of infection. The resulting index included three domains: pain, urinary symptoms, and quality of life. Pain domains include pain in the perineum, lower abdomen/suprapubic area, testes, penis, pain with ejaculation, and dysuria. The other two sections include voiding symptoms and interference/quality of life. It has been validated (Litwin, 2002), and the pain and quality of life subscales are sensitive to change (Propert et al., 2006).

Prevalence of Individual Symptoms in Men With Chronic Prostatitis and Chronic Pelvic Pain Syndrome

A large study of 1563 men with CP/CPPS in Europe and North America looked at symptoms reported on the NIH-CPSI (Wagenlehner et al., 2013). The mean

NIH-CPSI score in the group was 20.4. The most common location of pain was in the perineum 63.3%, testicular 57.6%, tip of penis 32.4%, suprapubic area 42.3%, dysuria 43.3%, and pain with ejaculation 47.7%. Patients with dysuria were significantly more likely to have ejaculatory pain (*P* < 0.001). Patients with a greater number of pain locations also had greater severity of pain, voiding symptoms, and worse quality-of-life scores. Frequency and intensity of pain had the highest impact on overall quality of life; urinary symptoms did not correlate with changes in quality of life. Overall, using the total pain domain score as a measure, 32% had mild pain, 52% moderate pain, and 16% severe pain.

Summary of Findings From the Multidisciplinary Approach to Pelvic Pain Study

The NIH-sponsored MAPP study recruited men as part of a large phenotyping study. A large battery of urologic and psychological questions was administered. Some of the important findings to date are the following:

1. Patients who have pain beyond the pelvis have more severe symptoms than those with pelvic pain only.

   The MAPP project used a whole body map to record sites of pain (Lai et al., 2017). Forty-five sites are designated on the body map divided into seven zones. The severity of the nonpelvic pain increased with the number of regions reported. Patients with a greater number of pain sites also reported significantly greater sleep disturbance, depression and anxiety, psychological stress, somatic symptom burden, and negative affect. They also had more symptoms consistent with IBS, fibromyalgia, and migraine headaches.
2. Men with COPC have more severe symptoms than those with only urologic symptoms.

   In the MAPP study, 31% of men with pelvic pain enrolled have one or more of these so-called COPCs, the most common being IBS; patients with COPC also report more severe urologic symptoms and more frequent depression and anxiety compared with those without COPC (Krieger et al., 2015).
3. Patients with bladder-focused symptoms (bladder pain with filling and painful urgency) report more severe symptoms than those who do not have bladder symptoms.

Of 191 men enrolled in the first MAPP study, 75% were found to have either painful urgency (i.e., urgency to urinate because of pain pressure or discomfort and not because of fear of leaking) or pain that was made worse with bladder filling (Lai et al., 2015). Compared with men with pelvic pain only, men with painful urgency or bladder pain had more flares and higher levels of catastrophizing and more frequently reported having IBS. They also had more severe symptoms of pain, frequency, and urgency. These symptoms are usually thought to be associated with interstitial cystitis/bladder pain syndrome, in which older studies have reported a 10 : 1 female-to-male ratio (Clemens, 2015; Hanno et al., 2011; Lai et al., 2015). In the RAND Interstitial Cystitis Epidemiology male study, there was a 17% overlap between men who met the high specificity IC/BPS definition and the case definition for CP/CPPS (Suskind et al., 2013). Thus there is considerable symptom overlap between CP/CPPS and IC/BPS as currently defined.

4. Pain and urinary symptoms should not be measured together as part of a composite score.

Principal components and exploratory factor analysis were used to examine questionnaire items that had been administered to participants in the MAPP study (Griffith et al., 2016). Exploratory factor analysis is used to identify a small number of factors that can explain a correlation matrix among a set of questionnaire items. The analysis suggested that two separate factors drove the correlations for the questionnaires, the first being pelvic pain and the second urinary symptoms. An association with depression was predicted by pain but not by urinary symptoms, indicating these symptoms vary in their impact on patients. The conclusion of this study was that it is important to assess pain and urinary symptoms separately rather than combined as in the present symptom questionnaires, the NIH-CPSI (Litwin et al., 1999) and the GUPI (Clemens et al., 2009). The implication for treatment trials is that if they used a combined score, as has been done for the majority of trials in CP/CPPS since 1999, then there may be significant effects on either pain or urinary symptoms that were not seen because the overall change in score was not clinically significant.

Fluctuations in Symptom Severity

In the MAPP study of 424 participants with urologic pelvic pain syndrome, of whom 191 were male, symptoms were assessed every 2 weeks for 1 year (Stephens-Shields et al., 2016). The percentage of patients who improved was 24.8% for pain symptoms and 15% for urinary symptoms. The percentages for those whose symptoms became worse were 9.4% for the pain and 6.1% for the urinary symptoms. Factors that were predictive of worsening symptoms at 1 year were the extent of widespread pain, the presence of nonurologic symptoms (COPC), and poorer overall health. Pain catastrophizing and self-reported stress were predictive of just worsening pain scores. There was no contribution of anxiety, depression, and general mental health to symptom worsening (Naliboff et al., 2017).

Significant exacerbations of symptoms have been termed *flares* (Sutcliffe et al., 2012). Many factors have been postulated to cause flares. In a case crossover study from the MAPP network, 79 reported no flare at baseline or at any time thereafter in the 1 year follow-up. In a group of 292 (69%) patients with at least one flare, 116 were men. Only recent sexual activity and UTI-like symptoms were predictive of flare. Issues that did not predict a flare included diet, physical activity or sedentary behavior, stress, and constipation (Sutcliffe et al., 2018).

Sexual Dysfunction

The prevalence of ED in men with CP/CPPS is reported at 15% to 40% (Tran and Shoskes, 2013). In addition, a case control study of a large Taiwanese health database showed that men with a diagnosis of ED were more likely to have been previously diagnosed with CP/CPPS, 8.6%, compared with 2.5% of randomly selected controls ($P < 0.001$) (Chung et al., 2012). Other symptoms of sexual dysfunction are ejaculatory dysfunction/pain and premature ejaculation. From the CPCRN cohort, 74% of the men had ejaculatory pain at some point (Shoskes et al., 2004). Similar levels of premature ejaculation have been reported (Tran and Shoskes, 2013).

Anxiety and Depression

In the original CPCRN cohort study, men with CP/CPPS were twice as likely to report anxiety and depression as age-matched controls (Pontari et al., 2005). Similar findings were reported in the subsequent MAPP study, as compared with age- and education-matched controls, males with pelvic pain showed greater levels of current and lifetime stress, poor illness coping, and increased self-report of cognitive deficits (Naliboff et al., 2015). A large database study from Taiwan found that men with CP/CPPS were significantly more likely to have a diagnosis of anxiety disorder than men without the diagnosis. The odds ratio (OR) was 2.10 (95% confidence interval [CI] 1.92–2.29, P <0.001). The association held for all age groups and was particularly strong in men aged 40 to 59 years old in which the OR was 2.53 (Chung and Lin, 2013).

Association With Other Medical Diseases

Cardiovascular Disease.

In the CPCRN study that compared cases with age-matched controls, men with CP/CPPS were six times more likely to self-report a history of cardiovascular disease, most commonly hypertension. A follow-up study by Shoskes et al. found greater arterial stiffness in men with CPPS compared with controls (Shoskes et al., 2011). The association of hypertension and CP/CPPS was also examined in the Health Professionals follow-up study, which found no association on multivariate analysis with hypertension overall, but there was in men with a BPH/LUTS history (OR 1.36) (Zhang et al., 2015). Other studies have been mixed, reporting no correlation for hypertension as part of metabolic syndrome in men with CP/CPPS (Wang et al., 2013) or a significantly higher rate of hypertension in men with CP/CPPS than controls (Chung and Lin, 2013).

Neurologic Disease.

Men with CP/CPPS were 5 times more likely to self-report a history of nervous system disease compared with asymptomatic age-matched controls in the CPCRN study (Pontari et al., 2005). In the NIH cohort, the symptom that most contributed to the difference in neurologic disease was numbness and tingling in the limbs. Also significant was a history of vertebral disk disease/surgery. Migraine headaches were common in the cases, but they were not significantly different than controls.

Phenotypic Approach to Symptoms and Symptom Clustering: UPOINT

The phenotype of patients meeting the criteria for CP/CPPS is variable and can include multiple different types of symptoms. This has been well outlined by Shoskes et al. in the UPOINT classification (Shoskes et al., 2009). This includes the categories of urinary, psychosocial, organ-specific, infection, neurologic/systemic, and tenderness of skeletal muscle (Fig. 56.5). The impetus for the classification was in part the recognition of the failure of monotherapies in clinical trials in men with CP/CPPS (Nickel et al., 2004). With this classification, therapy can be targeted to specific domains of symptoms. The clinical description of the UPOINT classification includes several factors under each domain, and descriptions of the compilation of symptoms have been published (Nickel and Shoskes, 2010). The percentage of men who fall in to each domain has been strikingly similar across multiple studies; the largest domain has been organ-specific and urinary, and the smallest domain has been the infectious category. Men with CP/CPPS generally are characterized by multiple domains. In an early description, only one in five men were positive for only one domain, one-third of men were characterized by two domains, and the rest by three or more domains (Shoskes et al., 2009). There is a strong correlation between the number of domains of UPOINT and severity of symptoms (Shoskes et al., 2009; Shoskes et al., 2010; Shoskes and Nickel, 2013).

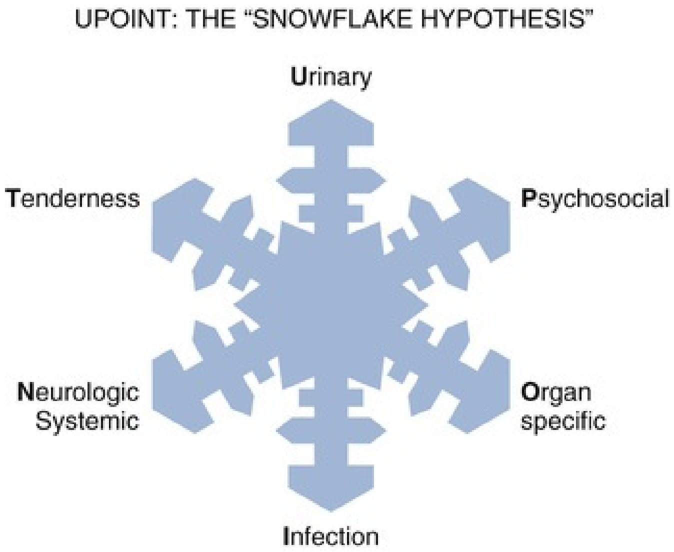

FIG. 56.5 The UPOINT classification has six clinically defined domains: urinary, psychological, organ-specific, infection, neurologic/systemic, and tenderness. Each individual patient has a unique phenotype, thus the idea of the "snowflake hypothesis." (Data from M. Pontari: *Common features*

and dissimilarities of urologic and other chronic pain syndromes: CP/CPPS, NIH meeting on phenotyping patients with pelvic pain, Baltimore, MD, June 2008.)

Evaluation of Chronic Prostatitis and Chronic Pelvic Pain Syndrome

CP/CPPS is a diagnosis of exclusion, and the evaluation must rule out identifiable causes of pelvic pain. To meet the NIH consensus definition, patients should not have active urethritis, urogenital cancer, urinary tract disease, functionally significant urethral stricture, or neurologic disease affecting the bladder (Krieger et al., 1999). A list of inclusion and exclusion and deferral criteria for diagnosis of CP/CPPS that have been used in NIH studies and trials were published by the CPCRN research network (Schaeffer et al., 2002).

Many other medical problems may be present in men with CPPS. One challenge for the urologist is that these include areas outside of the usual scope of urology, including neurologic, immunologic, and psychological factors that influence the disease process.

Two recent guidelines from the UK Prostatitis Expert Reference group (Rees et al., 2015a) and the International Consultation on Urologic Disease (Nickel et al., 2013) have published a description and recommendations for evaluation. The recommendations of these reports are incorporated into this description of the evaluation of CP/CPPS.

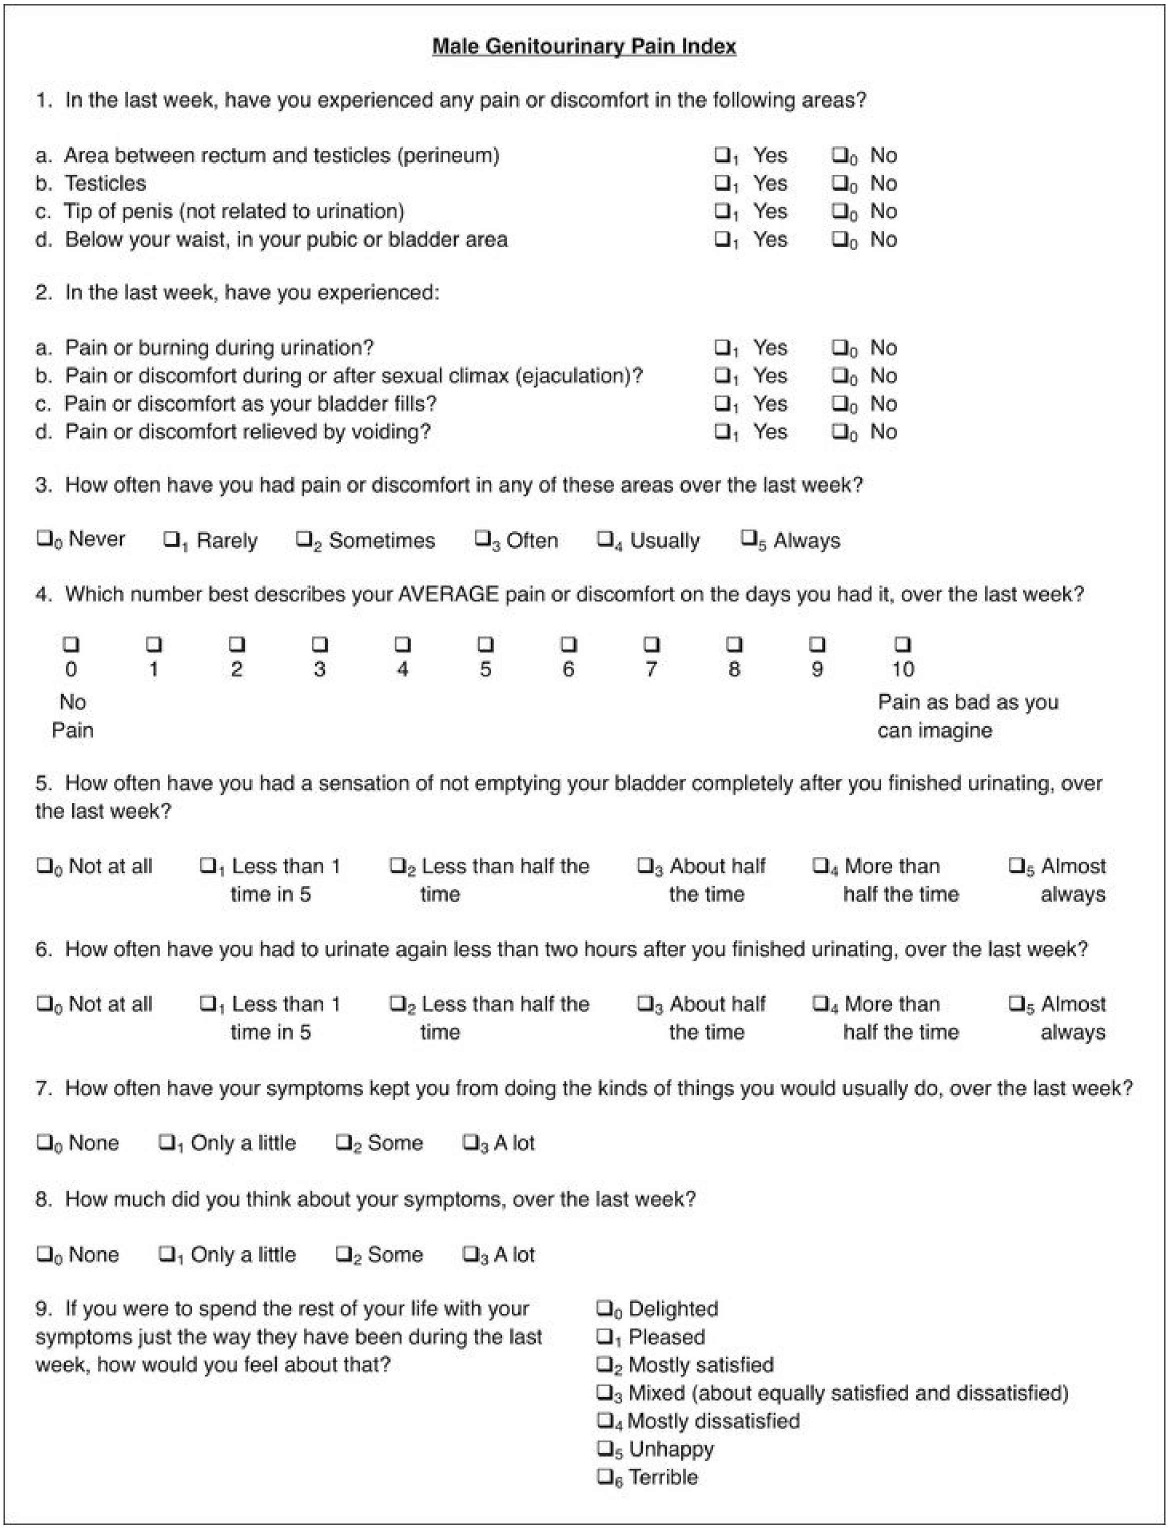
History

Given the wide variety of possible causes of CP/CPPS, information on possible cause can be obtained by a detailed history of the circumstances at the onset. Patients with onset associated with significant stress or psychological trauma may be more likely to have pelvic floor dysfunction. A history of trauma could indicate problems based on neurologic damage or musculoskeletal abnormalities. Some patients seek medical attention after a urinary tract infection or STD and should be assessed for persistence of infection.

Assessment

Pain.

The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) includes sections on pain including location, frequency and severity of pain, voiding symptoms, and interference/quality of life (Litwin et al., 1999). One limitation of the NIH-CPSI is that it does not have questions about pain thought to be related to the bladder. In the NIH-sponsored MAPP study, 42% of males enrolled at baseline met criteria for a diagnosis of IC/PBS (Krieger et al., 2015). A modification of the NIH-CPSI called the Genitourinary Pain Index (GUPI) (Fig. 56.6) contains two questions related to pain with bladder filling or emptying and better captures bladder symptoms (Clemens et al., 2009). The clinical importance is to remember to assess for symptoms of bladder pain in men with pelvic pain because this can prompt using bladder-specific treatments that are not useful in men with no bladder pain.



Male Genitourinary Pain Index

1. In the last week, have you experienced any pain or discomfort in the following areas?

a. Area between rectum and testicles (perineum)	☐$_1$ Yes	☐$_0$ No
b. Testicles	☐$_1$ Yes	☐$_0$ No
c. Tip of penis (not related to urination)	☐$_1$ Yes	☐$_0$ No
d. Below your waist, in your pubic or bladder area	☐$_1$ Yes	☐$_0$ No

2. In the last week, have you experienced:

a. Pain or burning during urination?	☐$_1$ Yes	☐$_0$ No
b. Pain or discomfort during or after sexual climax (ejaculation)?	☐$_1$ Yes	☐$_0$ No
c. Pain or discomfort as your bladder fills?	☐$_1$ Yes	☐$_0$ No
d. Pain or discomfort relieved by voiding?	☐$_1$ Yes	☐$_0$ No

3. How often have you had pain or discomfort in any of these areas over the last week?

☐$_0$ Never ☐$_1$ Rarely ☐$_2$ Sometimes ☐$_3$ Often ☐$_4$ Usually ☐$_5$ Always

4. Which number best describes your AVERAGE pain or discomfort on the days you had it, over the last week?

☐	☐	☐	☐	☐	☐	☐	☐	☐	☐	☐
0	1	2	3	4	5	6	7	8	9	10
No Pain										Pain as bad as you can imagine

5. How often have you had a sensation of not emptying your bladder completely after you finished urinating, over the last week?

☐$_0$ Not at all ☐$_1$ Less than 1 time in 5 ☐$_2$ Less than half the time ☐$_3$ About half the time ☐$_4$ More than half the time ☐$_5$ Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?

☐$_0$ Not at all ☐$_1$ Less than 1 time in 5 ☐$_2$ Less than half the time ☐$_3$ About half the time ☐$_4$ More than half the time ☐$_5$ Almost always

7. How often have your symptoms kept you from doing the kinds of things you would usually do, over the last week?

☐$_0$ None ☐$_1$ Only a little ☐$_2$ Some ☐$_3$ A lot

8. How much did you think about your symptoms, over the last week?

☐$_0$ None ☐$_1$ Only a little ☐$_2$ Some ☐$_3$ A lot

9. If you were to spend the rest of your life with your symptoms just the way they have been during the last week, how would you feel about that?

☐$_0$ Delighted
☐$_1$ Pleased
☐$_2$ Mostly satisfied
☐$_3$ Mixed (about equally satisfied and dissatisfied)
☐$_4$ Mostly dissatisfied
☐$_5$ Unhappy
☐$_6$ Terrible

FIG. 56.6 Genitourinary Problem Index (GUPI): Modification of the National Institutes of Health Chronic Prostatitis Symptom Index with addition of questions on bladder pain (with permission from Validation of a modified National Institutes of Health chronic prostatitis symptom index to

assess genitourinary pain in men and women. (From Clemens JQ; Calhoun EA; Litwin MS; McNaughton-Collins M; Kusek JW; Crowley EM; Landis JR; Urologic Pelvic Pain Collaborative Research Network. *Urology*. 74[5]:983–987, quiz 987.e1-3, 2009 Nov.)

Other Urologic Symptoms

Voiding: The NIH-CPSI and GUPI list only two questions on voiding dysfunction. The AUA symptom index can be useful to assess these other voiding symptoms (Barry et al., 1992).

Sexual function: The history should include an assessment including a history of erectile dysfunction, libido, and ejaculatory problems. The Sexual Health Inventory for Men (SHIM) instrument can be used to quantify the erectile dysfunction-reference (Cappelleri and Rosen, 2005). This is a shortened version of the International Index of Erectile Function (IIEF) (Rosen et al., 2002).

Review of Symptoms

Neurologic: Given the prevalence of neurologic disease in men in the CPCRN cohort, patients should be evaluated for concomitant neurologic disease (Pontari et al., 2005). A complaint of back pain with numbness or pain radiating down the legs should suggest lumbar-sacral disk disease. A history of migraine headache should be obtained. Changes in vision in a young male could suggest multiple sclerosis. Sensitivity to auditory, visual, or olfactory stimuli could also indicate underlying neurologic disease (Geisser et al., 2008).

GI: Men with CP/CPPS are more likely to have IBS (Rodriguez et al., 2009). There is overlapping innervation of the bowel and bladder such that irritation of the colon in experimental models results in inflammation of the bladder (Christianson et al., 2007). Irritation of one organ in experimental models results in inflammation of the other (Pezzone et al., 2005). The evaluation therefore of men with CP/CPPS must assess problems such as constipation, diarrhea, and the relation of discomfort to bowel movements. In the MAPP study, 31% of men had an associated chronic overlapping pain condition, the vast majority of which were IBS (Krieger et al., 2015). Men with GI symptoms can benefit from referral to a gastroenterologist, preferably one experienced in treating IBS. Thus asking about symptoms of IBS such as constipation, diarrhea, or both is important to help direct the patient to a GI specialist for treatment.

Rheumatologic: Men with CP/CPPS are at higher risk for systemic chronic pain syndromes such as fibromyalgia and chronic fatigue syndrome, although not nearly as increased a risk as IBS (Krieger et al., 2015). Fibromyalgia manifests as pain in many areas of the body. Pain with significant fatigue may indicate chronic fatigue syndrome. These conditions should be further evaluated by a rheumatologist.

Psychological symptoms: There are no published criteria for the psychological evaluation of men with CP/CPPS. However, men should be queried about significant anxiety, depression, and symptoms of obsessive compulsive behavior. Given the association of panic attacks with thyroid disease and interstitial cystitis, an assessment for panic attacks can be helpful (Weissman et al., 2004). A questionnaire that may be useful is the pain catastrophizing scale (Osman et al., 1997). Guidelines from the UK (Rees et al., 2015a) suggest using the Patient Health Questionnaire-9 (PHQ-9) (Moriarty et al., 2015) or a shortened version called the PHQ-2 and/or the Generalized Anxiety Disorder Screener-7 (GAD-7) (Lowe et al., 2008). They also offer several simple questions for initial assessment:

> **Anxiety:** In the past month, how often have you been bothered by feeling nervous, anxious, or on edge, or by not being able to stop or control worrying?
>
> **Depression:** In the last month, how often have you been bothered by feeling down, depressed, or hopeless? Having little interest or pleasure in doing things?

Physical Examination

Neurologic examination: Screening examination for abnormalities

Abdominal examination: To look for other causes of abdominal and/or suprapubic pain

Genitourinary examination: An examination for hernia, hydrocele, testicular masses, penile lesions, or other findings of the genitalia should be performed. A rectal and prostate examination should be performed. Rectal masses or hemorrhoids should be assessed. On rectal examination the prostate is tender in less than half of men (Shoskes et al., 2008); severe tenderness suggests acute prostatitis. Nodularity should not be attributed to inflammation and should prompt a consideration of prostate cancer.

Muscle tenderness: During rectal examination, palpation of the muscles lateral to the prostate and extending to the coccyx can identify myofascial trigger points and identify patients that may benefit from pelvic floor physical therapy and relaxation techniques (Berger et al., 2007). During palpation of the pelvic floor, having the patient abduct the leg on either side can make it easier to examine the muscles. An extended genitourinary pelvic floor examination has been evaluated with the MAPP study and detected pelvic floor tenderness in 47% of men with CP/CPPS compared with 6% of healthy controls. Prostatic tenderness was found in 22 of the cases and none of the controls (Yang et al., 2018). The importance of an extended examination is to maximize detection of pelvic floor tenderness, which can be amenable to pelvic floor physical therapy and targeted muscle relaxation treatments. The examination includes the perineal body, levator, obturator, and urogenital diaphragm muscles. The perineum was palpated midway between the anus and inferior edge of the scrotum. The pelvic floor muscles were palpated through the rectum: the urogenital diaphragm muscles were palpated anteriorly at the prostate apex; the obturator muscles were palpated anteriorly and laterally; the levator muscles were palpated posteriorly. The figure from the study is helpful as a roadmap to examination (Fig. 56.7).

(From Yang CC et al.: Physical examination for men and women with urological chronic pelvic pain syndromes: a MAPP network study. *Urology.* 116:23–29, 2018.)

Laboratory/Office Studies

Urinalysis: Men should have a urinalysis to look for unevaluated hematuria. A positive urine dip must be confirmed by finding 3 or more RBC per high-power field on a microscopic evaluation of the urine (Davis et al., 2012). Microscopy of the post-prostate massage urine (VB3) or expressed prostatic secretions have been used in the past to categorize men as category IIIA or IIIB; however, given the absence of clinical utility in making this distinction, this is not recommended.

Assessment for infection: A midstream urine sample for culture is recommended. If there is no documentation of culture results available, then a urinalysis and culture should be obtained at the time of symptom recurrence (Schaeffer, 2006). Optional in the UK guidelines but recommended by the International Consultation on Urological Diseases (ICUD) is the two-glass test, using the VB2 and VB3 specimens (Nickel et al., 2006). This is a standard diagnostic method in men with recurrent UTIs. Those men with a positive midstream urine culture, however, would be diagnosed with category II prostatitis, chronic bacterial and not category III CP/CPPS. The significance of a positive VB3 with a negative VB2 is unclear. This previously was considered to be a diagnosis of chronic bacterial prostatitis in older classification systems (Nickel and Moon, 2005). Asymptomatic men with no pelvic pain can be found to have positive localization cultures (Nickel et al., 2003). A positive VB3 has been used to classify as infectious in the UPOINT classification (Shoskes et al., 2009) and can be an indication for treatment with antibiotics (Shoskes et al., 2010).

Urine assessment for nontraditional organisms: It is not recommended to routinely send urine for culture for atypical organisms. However, in men who have a concomitant urethral discharge, nuclear amplification test should be performed for gonorrhea and chlamydia.

Semen cultures are not recommended.

Urine cytology: This is optional but indicated in men with irritative voiding symptoms such as frequency, dysuria, or hematuria. Carcinoma in situ of the bladder has been diagnosed in men presenting for evaluation of CP/CPPS, and hematuria is not always present (Nickel et al., 2002).

Postvoid residual: This should be checked by catheterization or ultrasound to rule out urinary retention as a cause of symptoms.

Blood tests: APSA test is not indicated. If, however, a PSA is measured and found to be elevated, the elevation should not be ascribed to CP/CPPS but should be further evaluated as in any patient (Nadler et al., 2006).

Imaging studies are optional and may be appropriate in some patients:

- **CT scan of abdomen and pelvis:** Patients with concomitant abdominal pain may require imaging with CT to exclude an intra-abdominal process such as chronic appendicitis or diverticulitis.
- **Scrotal ultrasound:** Testicular pain should be evaluated with a scrotal ultrasound.
- **Prostate ultrasound:** Transrectal ultrasound has limited utility in men with CP/CPPS (Nickel et al., 2013).
- **MRI of lumbar and sacral spine:** Patients with signs and symptoms of lumbar radiculopathy should be considered for MRI.
- **Uroflowmetry:** This is an optional study in the evaluation of CP/CPPS. It may be helpful in a young male with complaints of decreased force of stream as an investigation into stricture disease.

Urodynamics and cystoscopy: Urodynamics are optional studies used in men with CPPS. They should be used in those who fail medical therapy and have significant voiding symptoms, decreased uroflowmetry, and or elevated postvoid residual urine (Hruz et al., 2003). In addition to bladder outlet obstruction, urodynamics can also diagnose men with pseudodyssynergy, which is retained electrical activity of the external sphincter during voiding in the absence of abdominal straining; brief and intermittent closing of the membranous urethra during voiding detected by electromyography; or fluoroscopy in videourodynamics (Gonzalez and Te, 2006). These men are considered to have pelvic floor dysfunction.

Cystoscopy can be used in men with decreased uroflow and/or elevated postvoid residual urine to evaluate for urethral stricture. Cystocopy should also be used in men who give a history of pain with bladder emptying and/or relieved by bladder emptying, suggestive of IC/BPS because in a small set of these patients a Hunner's ulcer is present, which responds to fulguration or intralesional injections (Gonzalez and Te, 2006; Hanno et al., 2011).

Prostate biopsy is not recommended for the diagnosis of CP/CPPS alone.

Clinical phenotyping tool: UPOINT

The phenotype of patients meeting the criteria for CPPS is variable and can include several different types of symptoms. This has been well outlined by Shoskes et al. in the UPOINT classification (Shoskes et al., 2009). This includes the categories of urinary, psychosocial, organ-specific, infection, neurologic/systemic, and tenderness of skeletal muscle. This classification is a convenient way to remember the assessment and is also available online. The UK guidelines (Rees et al., 2015a) and ICUD summary (Nickel et al., 2013) recommend the use of UPOINT (or equivalent) as a means to phenotype symptoms and ultimately aid in directing therapy.

An outline of recommended tests sorted into mandatory, recommended, and optional categories is provided in Box 56.1.

Box 56.1

Evaluation for Men With Chronic Pain and Chronic Pelvic Pain Syndrome

Mandatory

History

- Pelvic pain: pain in penis, testes, suprapubic area, perineum; pain with bladder filling and/or relieved by bladder emptying; pain with ejaculation, dysuria, voiding symptoms
- Review of symptoms
    - Neurologic problems: changes in vision, back pain, numbness in legs or pelvis/perineum, migraine
    - GI problems: constipation or diarrhea, pain relieved by bowel movement
    - Rheumatologic: excessive fatigue, pain in many areas throughout body
    - Psychological: significant anxiety, depression, history of traumatic experience, pain worse with stress

Physical Examination

- GU examination for hernia, hydrocele, penile lesions
- Prostate nodules or tenderness
- Pelvic floor examination
- Abdominal examination for other sources of pain

Laboratory Studies

- Urinalysis to rule out hematuria reflex to formal urinalysis
- Urine culture

Recommended

- Symptom inventory: Use NIH-CPSI or GUPI
- Sexual function assessment
- Two-glass urine VB2 and VB3
- Flow rate
- Urine cytology for dysuria or gross hematuria
- Bladder ultrasound for postvoid residual urine

Not Recommended for Initial Evaluation in All Patients; Optional in Select Patients

- Evaluation for STD with nuclear amplification (urine)
- **Imaging studies**
    - Scrotal US for testicular pain or lesions
    - CT of abdomen/pelvis for abdominal pain
    - Transrectal ultrasound
    - MRI of lumbar/sacral spine for symptoms suggestive of disk herniation
- Other
- Urodynamics/flow rate and cystoscopy: for refractory voiding symptoms, elevated residual urine volume
- PSA: for prostate cancer screening

GI, Gastrointestinal; *GU*, genitourinary; *GUPI*, Genitourinary Pain Index; *PSA*, prostate-specific antigen; *STD*, sexually transmitted disease; *US*, ultrasound; *VB2*, midstream urine; *VB3*, post-massage urine.

Key Points

- CP/CPPS is a diagnosis of exclusion and should be made only after a thorough search for other causes of pelvic pain.
- CP/CPPS has potential issues outside of the pelvis (and usual scope of urology) such as psychological issues and neurologic problems.
- Patients with CP/CPPS must be assessed for other chronic pain syndrome such as irritable bowel syndrome, fibromyalgia, and chronic fatigue syndrome.
- Patients with tenderness on pelvis examination may benefit from pelvic floor physical therapy/myofascial release.
- Therapy for CPPS is best done in a multimodal fashion; the symptom classification UPOINT can be helpful in directing evaluation and subsequently therapy.

Treatment of Chronic Prostatitis and Chronic Pelvic Pain Syndrome

Pharmacologic Treatment

Antibiotic Treatment.

Small, uncontrolled studies have lent credence to the efficacy of antibiotic therapy in ameliorating patients' symptoms, but large randomized, placebo-controlled studies have failed to consistently show meaningful benefit. Studies without a placebo control that have shown a benefit include 500 mg of tetracycline combined with a nutraceutical and an ethylenediaminetetraacetic acid suppository for 3 months (Shoskes et al., 2005); 90 days of therapy with 200 mg levofloxacin or 200 mg levofloxacin plus 0.2 mg of tamsulosin in a study of 105 men with CP/CPPS (Ye et al., 2008); 6 weeks of levofloxacin 100 mg twice daily and combination with doxazosin 4 mg at bedtime (Jeong et al., 2008); the combination of ciprofloxacin 500 mg twice daily plus tamsulosin 0.2 mg (Kim et al., 2008); and a 6-week course of levofloxacin 200 mg twice per day or in combination with terazosin 2 mg before sleep (Wang et al., 2016).

There are relatively few placebo-controlled studies of antibiotics in the treatment of CP/CPPS. Only one of these showed a benefit. A randomized trial of levofloxacin 500 mg daily in 80 men with a diagnosis consistent with CP/CPPS found that NIH-CPSI symptom scores were not significantly improved after 6 weeks of therapy (Nickel et al., 2003). An NIH-sponsored trial randomized men with CP/CPPS and an NIH-CPSI score of at least 15 to ciprofloxacin 500 mg twice daily or placebo. The trial found that NIH-CPSI symptom scores were not significantly improved after 6 weeks of therapy (change in symptom score from baseline −5.4 versus −3.9 with placebo); additional changes 6 weeks later were minimal (Alexander et al., 2004). A third trial that showed a benefit looked at tetracycline HCL 500 mg orally per day combined with 0.4 g/day of vitamin C and 0.2 g/day of co-vitamin B compared with vitamin B used as a placebo. The premise of the trial was that the antibiotic plus vitamins would be effective against nanobacterial infection (Zhou, 2008).

Several questions arise in the use of antibiotics in CP/CPPS. One is whether there is a difference based on duration of a patient's symptoms and/or prior antibiotic exposure. Trials of antibiotics in men with shorter duration of symptoms have shown greater symptom benefit (Nickel and Xiang, 2008) than those in men with longer duration of symptoms (Alexander et al., 2004). Another question with using antibiotics in men with a clinical diagnosis of CP/CPPS is why they would work in this group of patients in whom the diagnosis requires UTI to be excluded by definition. Several factors have been proposed. One is that antibiotics, especially fluoroquinolones, have anti-inflammatory properties. Ciprofloxacin decreases IL-6 and tumor necrosis factor-alpha (TNF-α) production in cell lines, animal models, and in semen and postmasturbation urine samples in men with CP/CPPS (Ogino et al., 2009; Stancik et al., 2008). Another factor could be the effect of antibiotics on bacteria that are localized to the prostate fluid (VB3 or EPS) but not resulting in a positive midstream urine culture. These men are currently classified as category III; in older classifications such as the 1978 classification of Drach et al. they would have been classified as category II or chronic bacterial prostatitis (Nickel and Moon, 2005).

Several meta-analysis and systemic review studies have been published on the treatment of men with CP/CPPS. The data indicated that the greatest decrease in symptom score was seen in the combination of antibiotics and alpha-blockers, with a decrease in total NIH-CPSI of 13.8 points compared with placebo (Anothaisintawee et al., 2011). A follow-up analysis by the same group included some of the studies that used a comparator but not a lone placebo and reached a similar conclusion (Thakkinstian et al., 2012). Another meta-analysis included only the two controlled trials using fluoroquinolone antibiotics (Alexander et al., 2004; Nickel et al., 2003) and concluded that antibiotics failed to show statistically significant or clinically significant reduction in NIH-CPSI scores (Cohen et al., 2012). A meta-analysis that included all the trials listed above use a random effects model to account for the heterogeneity of the studies and concluded that antibiotics are not effective in the treatment of CP/CPPS (Zhu et al., 2014).

Fluoroquinolones have been the most widely studies antibiotics for this condition. The rationale for their use is originally based on their spectrum of activity as well as their pharmacokinetic properties allowing for high prostatic concentration (Charalabopoulos et al., 2003a). In patients with fluoroquinolone-resistant bacteria, trimethoprim alone (TMP), or in combination with sulfamethoxazole can be used. Other second-line agents include tetracycline, doxycycline, and macrolides (Nickel and Moon, 2005; Perletti et al., 2013).

Summary of Treatment Recommendations.

At the time of this writing, there were no AUA guidelines on the treatment of CP/CPPS. There are recommendations from the European Association of Urology (Engeler et al., 2013), which were antimicrobial therapy (quinolones or tetracyclines) over a minimum of 6 weeks in treatment-naïve patients with a duration of CPPS less than 1 year. The group convened by Prostate Cancer UK (Rees et al., 2015a) adds that a repeated course of antibiotic therapy (4 to 6 weeks) should be offered if a bacterial source is confirmed or if there is a partial response to the first course. Repeated courses of antibiotics in the absence of a positive urine culture is not accepted therapy.

Alpha-Blocker Treatment.

Alpha-blockers have long been used for treating CP/CPPS. The rationale includes the idea that some cases of CP/CPPS come from dysfunctional voiding (Lee et al., 2007). The α receptors in the central nervous system have also been shown to be active in long-term pain syndromes (Teasell and Arnold, 2004). Earlier randomized trials of alpha-blockers in men with CP/CPPS showed positive results, including those that used the NIH-CPSI score and those that predated its use. These include studies of terazosin (Cheah et al., 2003; Gul et al., 2001), doxazosin (Evliyaoglu and Burgut, 2002; Tugcu et al., 2007), alfuzosin (Mehik et al., 2003), tamsulosin (Chen et al., 2011; Nickel et al., 2004), and silodosin (Nickel et al., 2011).

Two large NIH-sponsored trials failed to show a benefit for alpha-blockers. Alexander found no benefit with tamsulosin in men who were treated for 6 weeks compared with placebo (Alexander et al., 2004). Men in this study were not necessarily alpha-blocker naive. A study of alfuzosin in men with shorter duration of symptoms and who were alpha-blocker naive did not show any benefit compared with placebo after 12 weeks (Nickel et al., 2008). Several meta-analyses have been published examining the use of treatments including alpha-blockers to show that there is no benefit (Cohen et al., 2012) or likely a benefit to using alpha-blockers, and the best results were in combination with antibiotics (Anothaisintawee et al., 2011) or with antibiotics and anti-inflammatory medications (Thakkinstian et al., 2012). **The ICUD study recommends alpha-blockers for newly diagnosed, alpha-blocker–naive patients who have voiding symptoms** (Nickel et al., 2013)**.The EAU guidelines recommend use of alpha-blockers for patients with a duration of PPS less than 1 year** (Engeler et al., 2013)**.**

Anti-Inflammatory Therapy.

The term *prostatitis* implies inflammation although only one-third of men with symptoms of CP/CPPS have inflammation on prostate biopsy (True et al., 1999). A randomized placebo trial of a cyclooxygenase (COX)-2 inhibitor, rofecoxib, which is no longer available because of cardiac side effects, showed the total and subscale NIH-CPSI scores significantly decreased from baseline in all groups, and no statistically significant difference was found. Patient global assessment of pain, a secondary outcome, favored rofecoxib over placebo (Nickel et al., 2003). A study of another COX-2 inhibitor, celecoxib, in a study of men with IIIA prostatitis showed significant reduction in total NIH-CPSI score, pain, and quality-of-life subscores, but not the urinary subscore (Zhao et al., 2009).

Other forms of anti-inflammatory medication have been tried. A small trial of 17 patients compared a leukotriene inhibitor, zafirlukast, to placebo in a study in which all patients also received doxycycline and found no difference (Goldmeier et al., 2005). A trial similar in size compared placebo with a 4-week course of prednisone with a dose reduction from 20 mg to 5 mg once per day over a 4-week period. No significant change in symptom scores was seen (Bates et al., 2007). A different approach to anti-inflammatory treatment was investigated in an observational study of beclomethasone diproprionate suppositories, a rectal form of corticosteroid. Clinically significant improvement in pain and voiding symptoms were seen in 162 of the 180 patients. No significant adverse effects were reported (Bozzini et al., 2016).

Results from meta-analyses indicate that anti-inflammatory medications are considered to have beneficial effects for some patients (Thakkinstian et al., 2012). They are likely ineffective if used alone but useful in combination therapy with an alpha-blocker and a muscle relaxant that also has anti-inflammatory properties (Cohen et al., 2012). The pooled RR for studies of anti-inflammatory medications for CP/CPPS was 1.8 (95% CI 1.2–2.6) compared with placebo (Anothaisintawee et al., 2011). **In conclusion, anti-inflammatory monotherapy is not recommended but can be used as part of multimodal therapy** (Nickel et al., 2013)**, but long-term side effects have to be considered** (Engeler et al., 2013).

Reductase Inhibitors.

A significant improvement with finasteride compared with placebo in the Prostatitis Symptom Severity Scale, a precursor to the NIH-CPSI, but not in pain was seen demonstrated in a small 12-month pilot study from Finland (Leskinen et al., 1999). A 6-month trial comparing finasteride with placebo in patients with category IIIA (defined as any inflammation in the EPS or VB3 specimen) at 4 academic centers showed improvement in symptoms compared with placebo but did not reach statistical significance (Nickel JC et al., 2004). Dutasteride at 0.5 mg was studied in the REDUCE trial, a 4-year, randomized, double-blind, placebo-controlled study of prostate cancer risk reduction. The NIH-CPSI survey was used to measure baseline and change in symptom severity. After 48 months, the dutasteride group noted a significant decrease of 6 points or greater in CPSI total score compared with placebo (49% vs. 37%, $P = 0.0033$) (Nickel et al., 2011).

Overall, 5α-reductase inhibitor (5ARI) medications appear to be effective in some patients. This is demonstrated when the previous trials are subjected to a meta-analysis, with significant reduction in NIH-CPSI scores compared with placebo (−4.6, 95% CI −8.7 to −0.5) (Anothaisintawee et al., 2011). The decision in whom to use 5ARI medications must also be made in the context of side effects, including reduced volume of ejaculate, erectile dysfunction, and decrease in libido (Thompson et al., 2003). This indicates that they may be best used in older patients with CP/CPPS who also have voiding symptoms from BPH (Rees et al., 2015a).

Medications for Neuropathic Pain.

Given the data to support a possible neuropathic basis for CP/CPPS, it is logical that medications used to treat neuropathic pain are commonly used for treatment. A randomized placebo-controlled trial of the anticonvulsant pregabalin in men with CPPS showed an effect that approached significance but did not reach the primary endpoint ($P = 0.07$) (Pontari et al., 2010). However, several secondary endpoints were significantly improved. This suggests that in a subset of men with CPPS, pregabalin may be effective (Berger, 2011). Patients with suspected neuropathic pain are commonly started on tricyclic antidepressants. Non–placebo-controlled studies have shown a beneficial effect of duloxetine when combined with tamsulosin and saw palmetto (Giannantoni et al., 2014) or with the alpha-blocker doxazosin (Zhang et al., 2017). Amitriptyline has been widely used in women with interstitial cystitis, but data in men with CPPS are lacking. In the IC/PBS studies, a better response was seen if the dose was increased up to 50 mg (Foster et al., 2010).

A phase IIa proof of concept clinical trial using tenazumab, a monoclonal antibody against nerve growth factor, in men with CPPS showed at week 6 there was marginal improvement in average daily pain and urgency frequency compared with placebo, with no difference in overall NIH-CPSI score (Nickel et al., 2012). A trial of an inhibitor of fatty acid amide hydrolase (FAAH), a synaptic membrane enzyme responsible for the breakdown of endogenous cannabinoids (eCBs), showed no improvement in pain reduction compared with placebo. However, there was greater improvement in voiding frequency compared with placebo in all groups tested (Wagenlehner et al., 2017).

Phototherapy.

Wagenlehner et al. compared treatment with the pollen extract Cernilton for 12 weeks to placebo and found significant improvement in total NIH-CPSI scores, as well as pain and quality-of-life domains (Wagenlehner et al., 2009). Similar results in a controlled trial were reported using another pollen extract product for 6 months, showing significant reduction in pain, voiding symptoms, and sexual function in the treatment group (Elist, 2006). The mechanism of action of pollen extract is unknown but is thought to induce smooth muscle relaxation and anti-inflammatory effects (Wagenlehner et al., 2011). Quercetin, a plant-derived bioflavonoid, showed a significant improvement in symptoms after 4 weeks compared with placebo in a small trial and also has been used in IC/PBS (Shoskes et al., 1999).

Bladder Specific: Pentosan Polysulfate.

Pentosan polysulfate (PPS) is a medication used to treat symptoms of interstitial cystitis, thought to work by augmenting the bladder's layer of glycosaminoglycans, which acts as a protective barrier. Use of PPS in men with CP/CPPS has shown modest improvement compared with placebo, with no significant changes in Clinical Global Improvement (CGI) scores but significant improvement in the NIH-CPSI quality-of-life scores (Nickel et al., 2005). It is recommended by the EAU guidelines but with a strength rating of weak (Engeler et al., 2013). For men with painful bladder filling relieved by emptying, consideration should be made to use treatments outlined in the AUA guidelines for treating interstitial cystitis (Hanno et al., 2011).

Other Medications

Allopurinol.

It was theorized that the intraprostatic ductal reflux of urine increases the concentration of metabolites containing purine and pyrimidine bases in the prostatic ducts, causing inflammation (Persson and Ronquist, 1996). Therefore allopurinol was compared with placebo in a randomized, double-blind controlled study in 54 men. The allopurinol groups had lower levels of serum urate, urine urate, and EPS urate and xanthine (Persson et al., 1996). However, re-review of the data and statistical methods showed that the changes in the urine and prostatic secretion of purine and pyrimidine bases resulted in significant amelioration of symptoms (Nickel et al., 1996). A follow-up randomized clinical trial further showed no advantage of allopurinol compared with placebo (Ziaee et al., 2006).

Mepartricin.

This is a mediation that reduces serum estrogen levels and prostatic estrogen receptors in animal models. One small trial indicated beneficial effects on total NIH-CPSI scores in men with CP/CPPS (De Rose et al., 2004).

PDE5 Inhibitors.

PDE5 inhibitors are useful to treat erectile dysfunction in men with CPPS at any age. Tadalafil can treat lower urinary tract symptoms, erectile dysfunction, and possibly the symptoms of CP/CPPS (Grimsley et al., 2007; Oelke et al., 2012). This may be of benefit in men with concomitant erectile dysfunction.

Other Treatments for Chronic Prostatitis and Chronic Pelvic Pain Syndrome

Conservative

Lifestyle Changes: Diet and Exercise.

In a survey of 62 patients with CPPS, 47% reported having sensitivity to some foods. The most common were spicy foods, coffee, tea, chili, and alcoholic beverages. Items that improved symptoms included docusate, psyllium (dietary fiber), water, herbal teas, and polycarbophil (fiber laxative) (Herati and Moldwin, 2013). There are no specific dietary recommendations for all patients with CP/CPPS, and they should be individualized based on the patient's food sensitivities. A study in men with CPPS demonstrated significant improvement in pain scores, quality of life, and overall NIH-CPSI scores in men in an aerobic exercise group compared with placebo/stretching after 18 weeks (Giubilei et al., 2007).

Stress Management/Psychological Treatments.

Of 134 men with chronic prostatitis treated with stress reduction alone, 110 (86%) reported that they were better, much better, or “cured” (Miller, 1988). Options for our patients with these psychological factors include traditional therapy with a psychologist or psychiatrist. A feasibility trial of cognitive therapy showed significant reduction in pain, disability, and catastrophizing in a small cohort of patients who completed an 8-week program (Tripp et al., 2011). Although not yet widely available, these types of program provide a promising future method of treatment, including using these treatments via the Internet (Perry et al., 2017).

Acupuncture.

The mechanism of the improvement in CPPS symptoms after acupuncture is unknown but can be postulated to have an ameliorating effect on neuropathic pain. Acupuncture for CP/CPPS is typically performed using 4 to 6 needle points (Herati and Moldwin, 2013). Controlled trials using sham needles placed at sites away from the true acupuncture sites have also shown a significant improvement over sham including increase in β-endorphin and leucine encephalin levels (Lee et al., 2011). The use of electrical stimulation in addition to needle placement has been used and shown to be superior to sham and advice and exercise alone in men with CPPS (Lee and Lee, 2009). A systematic review of trials of acupuncture in the treatment of CPPS identified 9 clinical trials involving 890 patients that met criteria for inclusion and concluded that the evidence for the efficacy of acupuncture for treating CPPS was encouraging, but the quantity and quality of the available evidence precluded making firm conclusions in favor of acupuncture (Posadzki et al., 2012). In clinical practice, given the relatively few side effects of acupuncture, it can be suggested to individuals who do not respond to first-line medical therapy or to those who would prefer to not take medications for their discomfort.

Minimally Invasive Therapies

Pelvic Floor Physical Therapy and Skeletal Muscle Relaxants.

Studies of noninvasive techniques to treat pelvic floor dysfunction include biofeedback and pelvic floor retraining, or learning to selectively contract and then relax the pelvic muscles. Reports of small series of this technique have shown significant improvement (Clemens et al., 2000; Cornel et al., 2005; Nadler, 2002). Results of pretreatment urodynamics and sphincter EMG were not predictive of outcomes (Clemens et al., 2000). Biofeedback and pelvic floor therapy are also effective in patients who have pseudodyssynergy on urodynamics (Kaplan et al., 1997).

A series of uncontrolled studies from Stanford have reproducibly shown a benefit to combining myofascial trigger point release and paradoxic relaxation training, essentially biofeedback training (Anderson et al., 2005). In addition to pain and urinary symptoms, improvements in sexual function including ejaculatory pain, decreased libido, or erectile dysfunction are also noted (Anderson et al., 2005; Anderson et al., 2006). A shorter 6-day course of myofascial release and trigger point manipulation has been described and produced a 6-point or greater decrease in total NIH-CPSI score at 6 months in 70 of 116 patients (60%) completing the course (Anderson et al., 2011).

One of the difficulties in assessing the effects of pelvic floor physical therapy (PT) is how to control the study. A study from the NIH-sponsored Urological Pelvic Pain Collaborative Research Network (UPPCRN) group showed the feasibility of using global massage as a control for patients undergoing myofascial physical therapy (Fitzgerald et al., 2013). Although not powered or designed to be a definitive outcome study, patients undergoing myofascial therapy had a significantly greater response on global assessment response than the therapeutic massage group, 57% to 21% ($P = 0.03$). **Referral to a physical therapist who is familiar with pelvic floor PT techniques, if possible, is recommended as the improvement after pelvic floor PT appears to be better after therapy received from specialized centers** (Polackwich et al., 2015b)**.**

Adjuncts to Pelvic Floor Physical Therapy.

For refractory cases of pelvic floor spasm, needling of the area, either as dry needling or with the injection of local anesthesia, can be used (Moldwin and Fariello, 2013). The use of perineal injection of *Botulinum* toxin has also been reported to relax tender muscle/trigger points (Gottsch et al., 2011). Other described methods to relax the pelvic floor include the use of extracorporeal shock wave therapy (ESWT). Early studies appeared promising (Zimmermann et al., 2008; Zimmermann et al., 2009), but a study looking at long-term results of ESWT in CP/CPPS patients demonstrated no benefit compared with sham control at 24 weeks as a follow-up to the same patient cohort that showed significant results at 12 weeks (Moayedinia et al., 2014).

Prostate Massage.

Prostate massage may help break up areas of ductal obstruction and help with flow and antibiotic penetrance into the prostate. Given the transrectal approach, it could also potentially have some effect on the pelvic floor. Uncontrolled studies (Nickel et al., 1999; Shoskes and Zeitlin, 1999) found clinical benefits in one-third to two-thirds of patients treated with repetitive prostatic massage (2 to 3 times per week) for 4 to 6 weeks along with antibiotic therapy. Other studies did not show a benefit when combined with antibiotics, in patients with either category II or III prostatitis (Ateya et al., 2006). **A subsequent systematic review of the literature concluded that evidence for a role of repetitive prostatic massage as an adjunct in the management of CP is, at most, "soft" but that the practice could be considered as part of multimodal therapy in selected patients** (Mishra et al., 2008).

Circumcision.

A study looked at the additive effect of circumcision to a regimen of antibiotic, anti-inflammatory, and alpha-blocker medications. A control group received medication only. A total of 774 men were randomized, and 713 completed the trial. At the end of 3 months, the percentage of men in each group with at least a 4-point drop in the NIH-CPSI score was 84.6% in the circumcision group and

68.5% in the control group ($P < 0.001$). Significant changes were seen in all three domains of the NIH-CPSI compared with the control group ($P < 0.001$) (Zhao et al., 2015). These data must be replicated, and the therapy is obviously limited to men who are not already circumcised but present an interesting adjunct to therapy.

Prostate-Specific Treatments

Local Hyperthermia and Needle Ablation.

In a series of 105 patients, those treated with transrectal radiofrequency hyperthermia with or without antibiotics for 6 weeks had a significant improvement in the domains of the NIH-CPSI compared with patients treated with antibiotics alone (Gao et al., 2012). Older studies have used microwave thermotherapy for CP/CPPS (Kastner et al., 2004; Michielsen et al., 1995; Suzuki et al., 1995). Few controlled trials are reported. Nickel and Sorensen reported that, at 3 months' follow-up, the transurethral microwave thermotherapy–treated patients had significantly improved symptom scores compared with sham-treated patients; 7 of 10 men treated with transurethral microwave thermotherapy had a favorable result compared with 1 of 10 men treated with a sham therapy (Nickel and Sorensen, 1996). Thermotherapy is not currently recommended for CP/CPPS but could be used in men with concomitant BPH. Transurethral need ablation (TUNA) has been used in men with CP/CPPS with mixed results (Chiang and Chiang, 2004; Chiang et al., 1997; Leskinen et al., 2002) and is not recommended for treatment.

Intraprostatic Injection of Onabotulinumtoxin A.

Recent studies have reported on intraprostatic injection of onabotulinumtoxin A (Botox). This has been used in the past for BPH. One small, uncontrolled study indicated that Botox worked better via a transrectal route than transurethral and in smaller glands (El-enen et al., 2015). Two controlled studies used the transurethral route. At a dose of 100 to 200 U there was significant benefit to the Botox injection compared with saline (Falahatkar et al., 2015) or cystoscopy without injection (Abdel-Maguid et al., 2018). Side effects included exacerbation of dysuria in almost half of patients, hematuria in 3% to 17%, and hematospermia in 7% to 14% (El-enen et al., 2015; Falahatkar et al., 2015).

Surgical Therapy for Chronic Prostatitis and Chronic Pelvic Pain

Syndrome

Surgical Therapy for Bladder Neck Hypertrophy.

Based on the possibility of centralization and lack of evidence of the prostate as a primary pain source in men with CPPS, transurethral resection is not expected to improve pain. One entity that may be important in a subset of patients is bladder neck hypertrophy. There are no pathognomonic diagnostic criteria. This should be suspected in men with chronic pelvic pain who also have significant obstructive voiding symptoms. Pressure flow urodynamics are expected to show increased voiding pressure and decreased flow, with a relative narrowing of the bladder neck (Hruz et al., 2003). It is important to rule out pseudodyssynergy, which would show inappropriate relaxation of the external urethral sphincter on EMG (Huckabay and Nitti, 2005). Te and Kaplan reported significant improvement in 31 of 32 men with bladder neck hypertrophy and symptoms of chronic prostatitis treated with bladder neck incision (Kaplan et al., 1994).

Neurostimulation.

Sacral nerve stimulation (SNS) and percutaneous tibial nerve stimulation (PTNS) are FDA approved for urinary symptoms but not specifically for pelvic pain. Most studies have looked at SNS in patients with interstitial cystitis/bladder pain syndrome and are case series. The implantation rate after test stimulation (>50% reduction in symptoms) ranges from 56% to 68%; of those implanted and followed for up to 5 years, 64% to 72% can achieve a durable, significant improvement (Yang, 2013). In a study of 89 patients with CP/CPPS randomized to PTNS or sham, there was significant reduction in pain, urgency, and NIH-CPSI score in the treatment group compared with the sham at 12 weeks (Kabay et al., 2009). An open trial of transcutaneous electrical nerve stimulation (TENS) was successful after 12 weeks of treatment in 29 (48%) patients, and a positive effect was sustained during a mean follow-up of 43.6 months in 21 patients (Schneider et al., 2013). At this time, it appears reasonable to offer PTNS as therapy in patients with CPPS and SNS in those with pelvic pain who also have urinary frequency and urgency.

Electromagnetic Stimulation.

In an open-label trial of electromagnetic stimulation, patients sat on a chair with electromagnetic energy for 30 minutes twice weekly for 6 weeks; 22 of 37 men demonstrated a greater than 6-point drop in NIH-CPSI compared with baseline at 24 weeks. Mean total and pain subscales were significantly improved at 24 weeks compared with baseline. International Prostate Symptom Score (IPSS) scores were also significantly improved compared with baseline (Kim et al., 2013). A previous study by Rowe showed a significant improvement in mean symptoms scores at 3 months and 1 year compared with the sham control group ($P < 0.05$) at 1 year (Rowe et al., 2005).

Cystoscopy and Fulguration of Hunner's Ulcer.

Men with pain thought to be of bladder origin (i.e., pain with bladder filling and/or relieved by bladder emptying) should have a cystoscopy to look for a Hunner ulcer. Although not commonly found, fulguration of these areas can provide symptom relief (Gonzalez and Te, 2006; Hanno et al., 2011).

Not Recommended: Radical Prostatectomy.

Not recommended is surgical removal of painful structures in the setting of pain elsewhere in the pelvis. Certainly **radical prostatectomy is not recommended in the absence of treatment for prostate carcinoma** (McLoughlin et al., 2014). A concern for pain relief is the possibility of neural centralization and that the prostate is not the isolated source of pain in these patients

Cochrane Review of Nonpharmacological Interventions for Treating Chronic Prostatitis and Chronic Pelvic Pain Syndrome

A 2018 Cochrane Database review examined the evidence for acupuncture, circumcision, electromagnetic chair, lifestyle modifications, physical activity, prostate massage, extracorporeal shockwave lithotripsy, and transrectal thermotherapy (compared with medical therapy). They did not find adequate information on psychological therapy or prostatic surgery. Their conclusion was that “some of the interventions can decrease prostatitis symptoms in an appreciable number without a greater incidence of adverse events. The quality of evidence was mostly low.” They encouraged future clinical trials with more detailed report of the methods, including sample size, masking, and outcomes including adverse events (Franco et al., 2018).

Treatment: Summary and Approach

A significant limitation to treatment of CP/CPPS is that there are no positive clinical trials for monotherapy in men with CP/CPPS (Nickel et al., 2013). Certainly therapy should start with the most conservative treatments possible, including lifestyle changes. Further therapy is best directed at simultaneous multimodal therapy based on the patient's individual phenotype (Shoskes et al., 2010). The UPOINT classification offers a convenient framework in which to plan treatment(s) and is recommended in current guidelines for treatment by the EAU (Engeler et al., 2013) and ICUD (Nickel et al., 2013). Finally, many if not most patients need to see more than one type of specialist. This often involves neurology, gastroenterology, psychiatry/psychology, physical medicine, and rehabilitation in addition to urology. Referral to a pain clinic, especially one with a multimodal approach may also be helpful (Baranowski et al., 2013). A referral to pain management specialists is also recommended if a patient requires the use of opioids.

Key Points

- Repeated courses of antibiotics in the absence of a positive urine culture are not indicated.
- The best treatment combination from meta-analyses is antibiotics plus alpha-blockers.
- Men with bladder pain should be considered for bladder-specific therapies.
- Men with tenderness on pelvic floor examination should be referred for pelvic floor physical therapy.
- Sacral neuromodulation can be used in men with pain who also have frequency and urgency.
- Treatment is best undertaken as simultaneous multimodal therapy addressing all aspects of the patients symptoms.

Acute and Chronic Orchitis and Orchialgia

Acute Orchitis

The incidence of acute orchitis is not known. In a recent review of 669 cases of acute scrotum in an emergency room over a 10-month period, patients were diagnosed with orchitis in 10.3% of cases and orchid-epididymitis in 28.7%; isolated epididymitis was diagnosed in 28.4% of the patients. The mean age of those in the orchitis group was 44.6 years old and for those in the orchidoepididymitis group, the mean age was 46.5 years old (Lorenzo et al., 2016).

Etiology

Acute orchitis can be divided into specific orchitis and viral orchitis. Specific orchitis can be caused by a wide variety of infectious diseases including by a hematogenous route. In a large series examining evaluation of the acute scrotum, men with orchitis and epipidymo-orchitis over the age of 35 most commonly have bacterial infection with predominantly gram-negative bacteria, *E. coli* and *Pseudomonas*, similar to the distribution of age and infection in acute epididymitis (Kaver et al., 1990). Other reported infectious agents include *Treponema pallidum* (Chu et al., 2016), *M. tuberculosis* (Yadav et al., 2017), and many others that are not common in the United States, including *Brucella* (Savasci et al., 2014) and *Filariasis* spp. (Richens, 2004). Candiduria can lead to epididymo-orchitis (Kauffman et al., 2011).

Viral orchitis is most commonly caused by the mumps virus (Ludwig, 2008). Despite vaccination that almost eliminated this disease by 2001, sporadic outbreaks have occurred since, involving a high percentage of persons with a history of vaccination (Cortese et al., 2011; Dayan and Rubin, 2008).The usual clinical scenario in Mumps is a prodrome of headache, malaise, and myalgias followed by parotitis developing 2 to 3 weeks after exposure and lasting for 2 or 3 days (Rubin et al., 2015). Orchitis is usually associated with epididymitis and fever, resolving within 1 week. Atrophy of the testis occurs in half the cases and can be associated with oligospermia and decreased fertility but usually not complete infertility (Dejucq and Jegou, 2001). Another virus that is associated with orchitis is the human immunodeficiency virus type 1 (HIV-1). This is the result of direct infection of the virus in the testis and as a consequence of immunosuppression from the infection (De Paepe et al., 1989). Orchitis is a symptom of infectious mononucleosis, indicating that the Epstein-Barr virus may have a direct effect on the testes (Cheung et al., 1993; Dejucq and Jegou, 2001). HSV-2 has been detected in the testes (DeTure et al., 1976). Many other viruses have been reported to infect the testes including dengue, smallpox, and chickenpox (Riggs and Sanford, 1962).

Autoimmune orchitis is defined as an autoimmune aggression of the testes characterized by the presence of anti-sperm antibodies (ASA). Conditions that produce symptomatic orchitis are classified as secondary autoimmune orchitis, as opposed to primary autoimmune orchitis, which is characterized by the presence of ASA, no associated systemic disease, and they are asymptomatic (Silva et al., 2014). Primary autoimmune orchitis is primarily a problem in the evaluation of male infertility. The main causes of secondary autoimmune orchitis are usually associated with a primary vasculitis, particularly Behçet's disease, polyarteritis nodosa, and Schönlein-Henloch purpura (Pannek and Haupt, 1997). The testis is an immune-privileged site, but in autoimmune orchitis the blood testis barrier is altered by a T cell–mediated inflammatory response with an increased production of proinflammatory cytokines such as IFN-g, IL-1, IL-6, IL-12, IL-17, and IL-23 and the resultant production of anti-sperm antibodies (Jacobo et al., 2011a; Jacobo et al., 2011b).

Evaluation

Medical history should include circumstances of onset, including sexual history, recent instrumentation or surgery, and prior episodes. A history of trauma should be elicited. The duration of pain is important given that one of the prime differential diagnoses is testicular torsion. A history of symptoms of upper respiratory symptoms and/or parotitis consistent with mumps should be established. Fever, sweats, headache, and back pain are common in infection with brucellosis (Street et al., 2017). Inquiry should also be made about a history of the multiple conditions that can cause secondary autoimmune orchitis. Physical examination should include assessment for signs of systemic involvement including fever and tachycardia. Examination of the scrotum usually reveals a tender testis and spermatic cord.

Urine culture should be obtained in all patients. Urine culture has been reported to be positive in 38.5% of patients diagnosed with isolated orchitis and

37.5% of those diagnosed with orchidoepididymitis (Lorenzo et al., 2016). In sexually active patients, especially with epididymal involvement, testing for STD should be performed. Imaging with scrotal US can help to distinguish testicular torsion from orchitis and identify testicular tumors and abscess (Altinkilic et al., 2013).

Treatment

In patients with signs of infectious orchitis, antibiotics to treat gram-negative uropathogens should be started and treatment adjusted based on the result of urine culture. In patients with suspicion of STD, especially younger patients with concomitant epididymitis, treatment for STD should be started (Centers for Disease Control and Prevention, 2015). Mumps orchitis can be treated by interferon but does not always prevent testicular atrophy (Ku et al., 1999). Secondary autoimmune orchitis may be treated with systemic medications, including corticosteroids, immunosuppressive medications such as azathioprine, or IV cyclophosphamide, and intravenous immunoglobulin (Silva et al., 2014). In men with HIV, treatment requires initial antibiotic treatment followed by a period of maintenance suppression, particularly if salmonella is identified as the causative organism (Shindel et al., 2011). Patients with orchitis need to be followed up, especially those whose symptoms do not resolve to rule out missed torsion or testicular tumor. Patients should also be counseled that, although the acute pain can resolve in 1 to 3 days, the ensuing inflammation can last 2 to 4 weeks before completely resolving (Trojian et al., 2009).

Chronic Scrotal Pain Syndrome: Orchialgia

Orchialgia is defined as scrotal pain, intermittent or constant, lasting at least 3 months, and can be unilateral or bilateral (Kavoussi and Costabile, 2013). **One of the first considerations in assessing orchialgia is to determine if the pain is limited to the testis/scrotum or if it is part of a larger pelvic pain problem including other pain sites consistent with CP/CPPS** (Clemens JQ et al., 2009; Litwin et al., 1999).

Epidemiology

In Europe, orchialgia accounts for 2.5% to 4.8% of clinic visits (Ciftci et al., 2010; Strebel et al., 2005). The prevalence in the United States is not known, but Zermann et al. reported in one series that almost 40% of chronic pelvic pain localizes to the scrotum (1999). Approximately 100,000 cases per year are estimated in the United States. The breakdown of known causes reported are 6% to 12% after vasectomy, 18% after inguinal hernia repair, up to 5% after scrotal surgery, and 1% to 2% after abdominal or groin surgery (Parekattil et al., 2013). The most common age for presentation is 20 to 30 years old (Calixte et al., 2017).

Cause of Chronic Orchialgia

There are multiple identifiable causes of chronic scrotal pain. Short-term scrotal pain, which lasts a few weeks, can occur in 30% of men undergoing a vasectomy, whereas developing into long-term chronic pain that causes men to seek treatment is reported in anywhere from 1 in 1000 men (up to 15%) (Kavoussi and Costabile, 2013; Tandon and Sabanegh, 2008). Other causes include iatrogenic injury after hernia repair in up to 14% of cases or laparoscopic surgery, and inguinal hernia repair in 18% of patients, with a greater risk in patients who undergo surgery for a recurrent hernia or in which mesh was used (Dickinson et al., 2008; Massaron et al., 2007). Orchialgia can also occur after varicocele or varicocele surgery, referred pain from a mid or distal ureteral stone, indirect hernia, aortic or iliac artery aneurysm, trauma, and/or perineural fibrosis (Sigalos and Pastuszak, 2017). Another more recent finding has been that of pelvic floor dysfunction. In a series of men with chronic orchialgia, 93% had at least one symptom of pelvic floor dysfunction, and 88% were found to have increased resting pelvic floor muscle tone (Planken et al., 2010). Approximately 18% to 25% of chronic orchialgia is considered idiopathic (Quallich and Arslanian-Engoren, 2013).

The importance of alterations in nerve function may be very important in the pathophysiology and subsequent management of chronic orchalgia. Parekattil et al. (2013) reported on the finding of Wallerian degeneration (WD) on nerve biopsy in a significantly greater proportion of patients with pain (84%) than controls (20%) (*P* = 0.0008). Also, the degeneration appeared to be in reproducible patterns, involving the cremasteric muscle layer, perivasal tissues, and posterior periarterial/lipotamous tissues, the so-called “trifecta nerve complex.” WD is a well-coordinated response of a nerve to injury, including proliferation of Schwann cells, changes in the local extracellular matrix, and recruitment of neurotrophin and cytokines, to facilitate axonal regeneration (Dubovy, 2011). The subsequent neuroinflammation can also lead to neuropathic pain. However, because 20% of the asymptomatic control group also had degeneration, this is not always the case (Parekattil et al., 2013). Staining with calcitonin gene-related peptide (CGRP), which is a marker of sensory nociceptors (Greco et al., 2008), has found increased levels of CGRP-positive nerves in spermatic cords of patients with pain compared with those with no testicular pain (Oka et al., 2016).

Granulomatous orchitis is marked by the presence of granulomatous inflammation in the testis and has multiple causes, including tuberculosis, brucellosis, actinomycosis, syphilis, leprosy, and sarcoidosis (Akinci et al., 2006; Roy et al., 2011). Idiopathic granulomatous orchitis is a rare inflammatory condition of unknown cause characterized by nonspecific granulomatous inflammation with multinucleated giants cells without caseation (Roy et al., 2011). Diagnosis is usually made after orchiectomy for suspected malignancy as the presentation is similar on ultrasound. Patients may have chronic pain but may also present with painless testicular enlargement (Dhand and Casalino, 2011). Just as has been described in the prostate, IG4-related inflammation has emerged as the cause of scrotal content pain, affecting the testis cells (de Buy Wenniger et al., 2013) and perivasal tissue-causing fibrosis (Najari et al., 2014). IG4-positive cells have also been reported in specimens of idiopathic granulomatous orchitis in men with no history of systemic IG4 disease (Karram et al., 2014). Another inflammatory condition that can cause orchitis is malakoplakia. The distinction from granulomatous orchitis is a dense infiltrate of histiocytes, and pathognomonic Michaelis-Gutmann bodies (Roy et al., 2011).

Evaluation

The diagnosis is directed at ruling out the other causes of chronic orchalgia. A history should evaluate for signs and symptoms of intermittent torsion and for infection with history of prior testicular or epididymal infection. On review of systems, the presence of symptoms of bowel dysfunction with constipation or diarrhea that may be indicative of IBS should be asked (Ciftci et al., 2010). Also important are symptoms of lower back pain and vertebral disk disease, because orchalgia can be referred pain from back problems (Rowell and Rylander, 2012). LUTS could indicate a history of voiding dysfunction, which could lead to UTIs. Cui and Terlecki reported that on screening for low testosterone or B12 levels in men with chronic orchialgia, 125 of 154 were found to be deficient in either or both compounds (Cui and Terlecki, 2016). A thorough examination of the genitalia including testes, epididymis, prostate, and pelvic floor is mandatory. Inguinal hernias should be ruled out. Laboratory studies include a urinalysis**. A**

duplex Doppler ultrasound should be performed to assess for anatomic or congenital abnormality, or mass (Costabile et al., 1991b). If a ureteral stone is suspected, a CT scan can be performed.

Therapy for Idiopathic Orchialgia and Chronic Scrotal Pain Syndrome

Medical Therapies.

Much like CP/CPPS, antibiotics are commonly used but rarely indicated (Strebel et al., 2005). Doxycycline and quinolones are recommended because of their penetration into the scrotal structures and because they can be used for up to 4 weeks (Levine, 2010). Anti-inflammatory medications are commonly used for the analgesic effects. There is little supporting evidence however for a specific therapeutic target (Starke and Costible, 2017). Given that CSPS is a chronic pain condition, medications used for neuropathic pain are prescribed. These include tricyclic antidepressants and gabapentin (Costabile et al., 1991a).

Spermatic Cord Block.

When the initial evaluation does not show a discrete treatable cause and conservative medical management does not improve symptoms, a reasonable next step is spermatic cord block with bupivacaine. If positive, this can help confirm the diagnosis of orchialgia (Sigalos and Pastuszak, 2017). It may also help predict if spermatic cord denervation will be effective as a treatment. In a series of 74 patients, a positive response to a spermatic cord block with more than 50% temporary reduction in pain was an independent predictor of pain response to microsurgical denervation of the spermatic cord (MDSC) (Benson et al., 2013).

Surgical therapy: see the following for nonpharmacologic treatment of chronic scrotal pain.

Acute and Chronic Epididymitis (Epididymalgia)

Acute Epididymitis.

Acute epididymitis is defined as pain, swelling, and inflammation of the epididymis that lasts more than 6 weeks. Epididymitis is a common condition. The incidence rates range from 25 to 65 per 10,000 person years and accounts for up to 600,000 cases per year in the outpatient setting in the United States (Cek et al., 2017). The average age of acute epididymitis is variable and affects pediatric and adult populations.

Etiology.

The widely accepted route of infection is the ascent of microorganisms from the urethra, as reported by Campbell in 1927 in cases of gonococcal urethritis and subsequent epididymitis (Centers for Disease Control and Prevention, 2015). This was confirmed in later studies that compared isolates from the urine/urethra and simultaneously epididymitis and identified concurrence between the areas of approximately 80% (Berger et al., 1987; Doble et al., 1989a; Melekos and Asbach, 1987).

The causative organisms depend on the age of the patient. The classic teaching has been that men over the age of 35, as well as in children, the organisms are similar to those causing a urinary tract infection, such as *E. coli*. In men under 35 who are sexually active, *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are more common (Holmes et al., 1979). Risk factors in the older men without sexually transmitted epididymitis include history of prostate infections or UTIs, recent surgical intervention in the urinary tract, bladder outlet obstruction such as BPH or stricture, uncircumcised penis or congenital deformity of the urinary tract, and immunosuppression (Ryan et al., 2018).

An updated examination of the causes of epididymitis was recently undertaken by a German group, using updated diagnostic methods for bacteria and viruses (Pilatz et al., 2015). A bacterial pathogen was found in 130/150 patients (87%), the most common was *Escherichia* (56%). The most common sexually transmitted infection was *Chlamydia* followed by *Mycoplasma* and *N. gonorrhoeae*. The sexual history did not always match the diagnosis, and men under 35 had enteric organisms in 42% of cases. **The conclusions from this very well-executed study are the following:**

1. **The age cutoffs of younger than 35 for a sexually transmitted infection (STI) as cause of acute epididymitis and older than age 35 to have an enteric bacterial pathogen are not strict rules.**
2. **A sexual history suggests that STI is not predictive of STI and that men with STI may not have a convincing history. Therefore all sexually active men with acute epididymitis should be screened for an STI.**

3. **Viruses were not a significant contributing factor to acute epididymitis, and mumps were not detected.**
4. **13% of cases still had no identifiable microbial cause.**

Clinical Evaluation.

The signs and symptoms of acute epididymitis include pain and swelling. Swelling usually starts at the cauda of the epididymis and then ascends to reach the rest of the epididymis and then to the testis. Presentation is unilateral in 96% of cases (Cek et al., 2017). In the large series of Pilatz et al., 26% of patients presented with a fever defined as greater than 38°C, whereas 6.7% presented with an epididymal abscess (Pilatz et al., 2015). Dysuria is reported in one-third of patients (Kaver et al., 1990; Pearson et al., 1988).

Medical history should include circumstances of onset, including sexual history, recent instrumentation or surgery, and prior episodes. Physical examination should include assessment for signs of systemic involvement, including fever and tachycardia. Examination of the scrotum usually reveals a tender epididymis and spermatic cord. Induration of the cauda or whole epididymis is frequently present, and orchitis is noted in half of cases (Kaver et al., 1990).

Diagnostic evaluation should include laboratory studies to assess for white blood cell count, urine for routine urine culture and susceptibility, assessment of inflammation by leukocyte esterase on first-void urine or microscopic examination of sediment from a spun first-void urine (Centers for Disease Control and Prevention, 2015). In older men with acute epididymitis, an assessment of postvoid residual urine should be made to rule out urinary retention as a cause of UTI and subsequent epididymitis.

The differential diagnosis of acute scrotal pain such as seen with acute epididymitis includes testicular torsion, torsion of the appendix testis, inguinal hernia, testicular carcinoma, pain from varicocele, scrotal or testicular abscess, acute orchitis, and/or testicular trauma (Cek et al., 2017). Imaging studies include scrotal ultrasound. Common ultrasound features include hydrocele, epididymal enlargement, hyperperfusion, and testicular involvement (Pilatz et al., 2013). This is an important tool to confirm the diagnosis and to rule out testicular torsion as a cause of the acute scrotal pain (Altinkilic et al., 2013).

Treatment.

For symptom relief, the traditional recommendations are bed rest, elevation of the scrotum, and local cooling. Nonsteroidal anti-inflammatory medications can also be useful. Most patients can be managed on an outpatient basis, but those with elevated white blood cell counts and fever should likely be admitted. Antimicrobial therapy depends on the most likely pathogen. The CDC guidelines divide this into three groups: acute epididymitis likely caused by STD, likely caused by STD and enteric organism (men who practice insertive anal sex), and likely only caused by enteric organisms. For the first group, the recommendation is ceftriaxone 250 mg in single IM dose plus doxycycline 100 mg orally twice per day for 10 days; for the second group levofloxacin 500 mg PO daily (or ofloxacin 300 mg PO twice per day) for 10 days is substituted for doxycycline, and for the third group levofloxacin (or ofloxacin) alone is recommended. Men with confirmed chlamydia or gonorrhea should also be tested for other STDs including HIV, and their sex partners should also be referred for evaluation and presumptive treatment (Centers for Disease Control and Prevention, 2015).

Follow-Up.

It is recommended that men whose symptoms do not resolve within 72 hours be re-evaluated. Follow-up ultrasound may be needed in patients who are not clinically responding to rule out progression of an infection to an abscess or testicular infarction, which would require surgical treatment. Close follow-up of urine cultures for susceptibility is also important given the increasing rates of fluoroquinolone-resistant bacteria (Ryan et al., 2018).

Chronic Epididymitis.

The definition of chronic epididymitis is similar to that for orchalgia (i.e., symptoms of discomfort and/or pain for at least 3 months' duration), localized to 1 or both epididymis (Nickel et al., 2002). In a survey of Canadian urologists over a 2-week period, of 6037 male patients seen, 57 or 0.9% had chronic epididymitis with a mean duration of 2.5 years and an average age of 41.1 years (Nickel et al., 2002).

Etiology.

Nickel et al. recommended a classification of chronic epididymitis as being one of three categories: inflammatory, postobstructive, and chronic epididymyalgia, implying no clear cause (Nickel et al., 2002). Causes in the inflammatory group include infective from chlamydia, postinfective after acute bacterial epididymitis, granulomatous from tuberculosis, drug-induced from amiodarone, and idiopathic inflammatory. Patients with AIDS are also prone to develop tuberculous epididymitis (Heyns et al., 2009). The postobstructive group includes pain associated with congenital, acquired, or iatrogenic obstruction, such as postinfective or postsurgical, including postvasectomy.

Evaluation.

Medical history should include any history of treatment for acute epididymitis. A Chronic Epididymitis Symptom Index has been published (Nickel et al., 2002). In the Canadian classification of epididymitis, the inflammatory chronic epididymitis is associated with abnormal swelling or induration. The obstructive may have induration, and in the idiopathic group or epididymalgia, the epididymis is palpably normal (Nickel et al., 2002). Patients may also experience testicular pain. Specific to tuberculous epididymitis, the onset is described as subacute, with swelling of the epididymis that may not be painful. Systemic signs of TB, along with scrotal thickening and a characteristic fistula, may be present. A scrotal mass may be present. Although TB often commonly involves the testis, the epididymis is solely infected in 45% of cases (Yadav et al., 2017). Laboratory tests include a urinalysis and midstream urine for culture. Patients with a urethral discharge should be evaluated with testing for an STD. Imaging studies including scrotal ultrasound are helpful to look for epididymal and testicular tumors. Patients should be assessed for neurologic problems that contribute to the pain, especially back pain indicating disk disease (Calixte et al., 2018).

Treatment.

Conservative measures are recommended to start. Ruling out a malignancy allows for counseling the patient on the benign nature of the condition and observation if symptoms are mild. Scrotal support and warm compresses may be beneficial. Medical treatments lack evidence-based studies. Many types of medications have been used including antibiotics, anti-inflammatories, phytotherapy, and anxiolytics (Cek et al., 2017). Approximately one-quarter of patients receive pain medications (Nickel, 2003).

Tubercular Epididymitis

The EAU has published guidelines for the treatment of genitourinary TB (Kulchavenya et al., 2016). Medical treatment is with anti-TB regimens of antibiotics. The usual regimen is 4 anti-TB drugs simultaneously for a minimum of 6 months. Five different regimens of chemotherapy are used depending on the form of urogenital TB. Surgery to drain an abscess may be needed, or removal of a chronically infected epididymis or testis may be necessary. All surgical procedures should be performed while on anti-TB medications. The treatment duration is then judged based on the histology of the removed tissue. **An indication for surgery is failure of a scrotal mass to respond or increases in size after 3 weeks of antitubercular chemotherapy; the mass should be explored by an inguinal incision to rule out testicular or epididymal malignancy** (Cek et al., 2005).

Nonmedical Therapy for Chronic Scrotal Pain: Chronic Orchitis (Orchalgia) and Chronic Epididymitis (Epididymalgia)

Minimally Invasive Treatments

Pelvic Floor Physical Therapy.

Given the results of a study of 41 men with chronic testicular pain showing increased resting pelvic floor tone (Planken et al., 2010), **pelvic floor PT should be considered in men with orchlgia and abnormal tone on digital rectal examination.** A series of 30 patients with chronic orchalgia treated with pelvic floor physical therapy reported that after 12 sessions, pain improved in 50% of men, and complete resolution of pain occurred in 13% (Farrell et al., 2016).

Botox.

Local cord denervation with onabotulinumtoxin A (Botox) has been used for chronic scrotal pain. Khambatil et al. reported on 18 patients with chronic scrotal pain with a cord injection of Botox. All patients had experienced temporary relief from a cord block of 0.5% Marcaine and 2% xylocaine. One hundred units of Botox were injected 1 to 2 cm distal to the external ring, targeting the branches of the genitofemoral and ilioinguinal nerves. At 1 month follow-up pain was reduced in 72% of patients, and at 3 months in 56%. Most men had return of pain and tenderness by 6 months (Khambati et al., 2014).

Pulsed Radiofrequency of the Spermatic Cord.

Pulsed radiofrequency has been performed for chronic back pain and sciatica, as well as for chronic visceral pelvic pain. Five patients with chronic scrotal pain (one bilateral) who responded to local anesthetic cord block were treated with pulsed radiofrequency (PRF) denervation of the spermatic cord. The treatment time was 3 minutes at 42 °C. At a mean follow-up of 25 weeks, the mean visual analog scores for pain decreased from 9 to 1. No complications such as testicular atrophy or decreased sensation of the scrotal or penile skin were reported (Basal et al., 2012). There are no long-term results available with this technique.

Nonradical Surgical Treatments

Neuromodulation

A sacral nerve stimulation trial that entered the caudal epidural space resulted in an 80% decrease in pain at 4 months in a male with recurrent epididymitis (McJunkin et al., 2009). Although the stimulator works on the S2-S4 area, the result with the testis was attributed to recent re-evaluation of dermatomes that reports that dermatomes are larger than described in most textbooks (Lee et al., 2008) and that based on cadaver studies, 25% of pudendal nerves receive a contribution from S1 (Shafik et al., 1995). Spinal cord stimulation in the epidural space to the level of T10 and T11 has been reported to help chronic scrotal pain (Nouri and Brish, 2011) as has cutaneous stimulation of the cutaneous branch of the ilioinguinal and genital branch of the genitofemoral nerves (Rosendal et al., 2013).

Surgical Therapy

Surgical Therapy for Orchalgia in Patients With Identifiable Intrascrotal Lesions

Patients can present with pain that appears to be localized to specific lesions (i.e., a varicocele or spermatocele). Patients can also have surgery for intermittent torsion. The results of surgery for pain resulting from hydrocelectomy, spermatocelectomy, and orchidopexy for intermittent torsion are reported as 100%, 94%, and 89%, respectively (Gray et al., 2001). The most common surgery for a specific target is spermatic vein ligation for treatment of a painful varicocele with a complete resolution rate of 85% by primary microsurgical and 72% for nonmicrosurgical repair; for laparoscopic repair the mean complete resolution rate is 81% with a recurrence rate of 6.8%

(Shridharani et al., 2012). Percutaneous embolization can be effective for painful varicocele, but recurrence rates are generally higher than for microsurgical repair. The rate of success for microsurgical repair as a salvage procedure for recurrent or persistent varicocele after varicocelectomy has been reported at 90% (Chawla et al., 2005). Predictors of response to varicocelectomy include greater number of veins ligated (>7), greater preoperative pain score (>6), and longer duration of pain (>9 months) (Chen, 2012).

Vasovasostomy or Vasoepididymostomy for Treatment of Postvasectomy Pain

An option unique to patients with postvasectomy pain syndrome is to reverse the vasectomy and restore patency of the vas. Complete response rates are 34% to 50%, and overall improvement is 82% to 93% (Horovitz et al., 2012; Lee et al., 2014; Myers et al., 1997; Nangia et al., 2000; Polackwich et al., 2015a). A 20% reoperation rate from 1 to 9 years was reported by Polackwich et al. (2015a). Pain relief may take 3 months or more after the procedure, an important point in counseling patients and managing expectations (Horovitz et al., 2012). Given the relatively minimal morbidity, this is an attractive option for patients who have persistent long-term pain after vasectomy in the absence of other identifiable causes.

Microsurgical Denervation of the Spermatic Cord

Microsurgical denervation of the spermatic cord (MDSC) was first described by Devine and Schellhammer in two patients in 1978 (Devine and Schellhammer, 1978). This procedure involves transecting the nerves in the spermatic cord, while preserving the blood supply and lymphatics to prevent formation of a hydrocele (Tan and Levine, 2016). The internal spermatic veins are ligated, and the cremaster muscle and spermatic cord fascia are preserved (Strom and Levine, 2008). **Three areas identified by Parekatil et al. that had the highest areas of WD were the cremasteric muscle fibers, the perivasal sheath, and the posterior lipomatous tissue; these areas were called the trifecta nerve complex, which is thought to form the anatomic basis for relief from the denervation procedure** (Parekattil et al., 2013). This approach has led to a more targeted MDSC approach in which the inner spermatic sheath is completely spared and only 5% to 10% of the spermatic cord is ligated, minimizing risk to the testicular and vasal arteries. A biowrap is also placed around the cord to minimize scarring and neuroma formation (Calixte et al., 2018).

Numerous studies on the efficacy of MDSC have been published (Benson et al., 2013; Larsen et al., 2013; Oomen et al., 2014; Parekattil et al., 2013; Strom and Levine, 2008) and report cure rates of 50% to 70%. By far the largest series is from Calixte et al., who report on 860 cases of robot-assisted microsurgical denervation. At a median follow-up of 24 months, complete resolution of pain was achieved by 49% of their patients, and 34% had a greater than 50% reduction in pain. The improvement in pain continued to progress with higher rates reported at 4 years than 6 months postoperatively (Calixte et al., 2018). Two studies have reported on specifically the results in men with postvasectomy pain syndrome, one from 1997 in which 13 of 17 reported complete relief of pain at the first follow-up visit and the other 4 had improvement (Ahmed et al., 1997). A much more recent report of overall success was achieved in 20/27 units. Patients with involvement of multiple structures in the scrotum (i.e., testis, epididymis, spermatic cord) had a success rate of 81% and were more likely to have a successful surgery ($P < 0.001$) (Tan et al., 2018). Men who have had a prior attempt at surgical repair at pain relief respond in a similar fashion to men who have not had any prior attempts at surgical therapy for chronic scrotal pain (Larsen et al., 2013; Tan et al., 2018).

Positive response to spermatic cord block predicts success with MSDC. The amount of pain relief obtained after cord block correlates with pain relief after undergoing MSDC, and those with a good response are likely to have durable and complete resolution of their pain (Benson et al., 2013). Some men may experience more pain relief with MSDC than cord block. The recommendation by Jonas et al. is to consider MSDC in men who have at least a 50% reduction in pain on spermatic cord block with 20 mL of 0.25% bupivacaine injected at the level of the pubic tubercle (Benson et al., 2013). Discussion of the risks and benefits are important because although the majority of results are good and there are few reported complications, one of those complications is testicular atrophy (Strom and Levine, 2008).

Epididymectomy for Chronic Pain

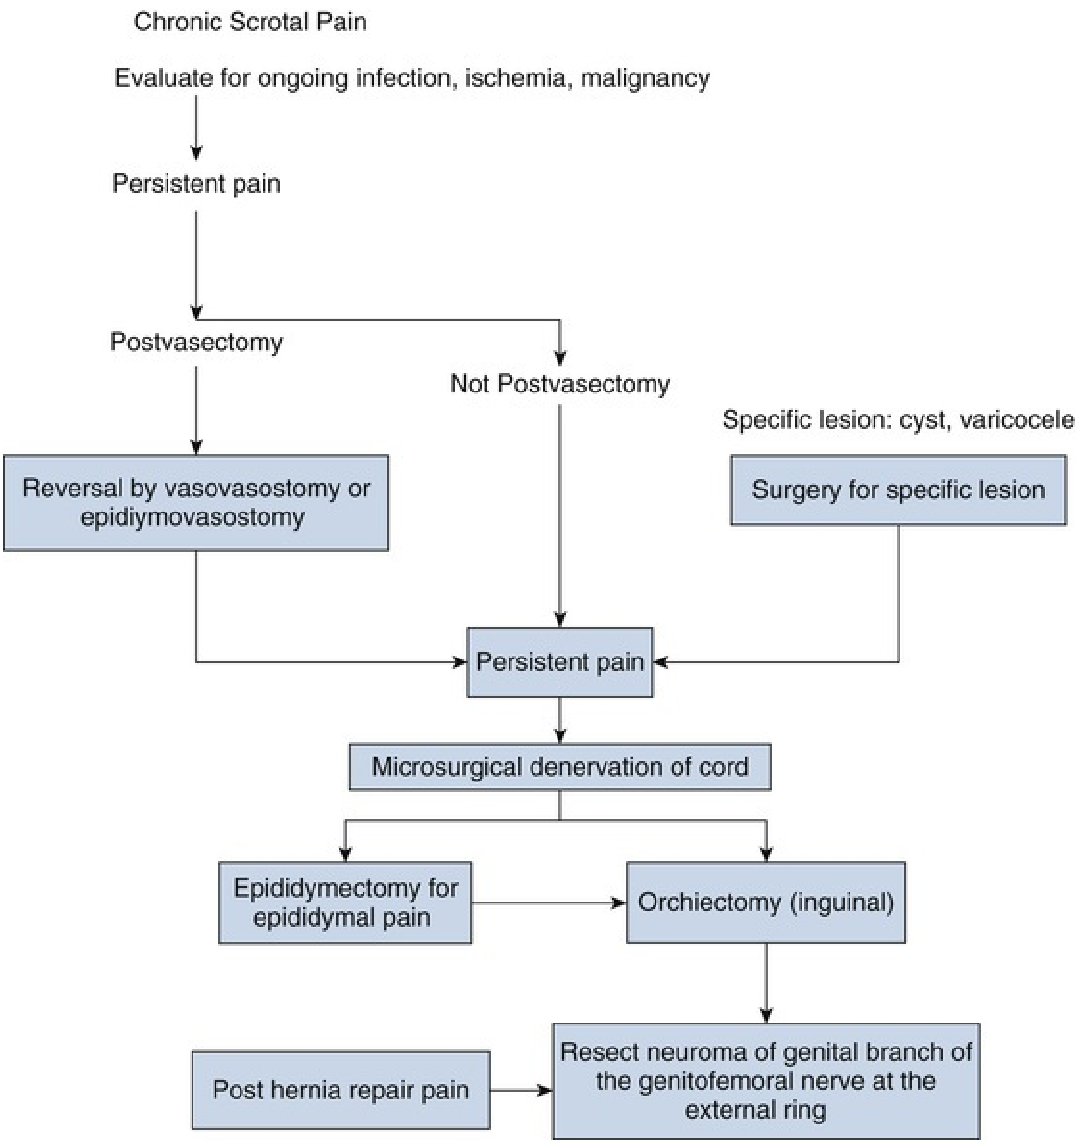
In the series of Davis of 10 patients who underwent epididymectomy, only 1 had significant pain relief and 9 subsequently underwent subsequent orchiectomy as definitive treatment (Davis et al., 1990). However, other series have reported better results. These range from 32% cure rate (Sweeney et al., 2008) up to 100% (Selikowitz and Schned, 1985). Most series report complete improvement in 50% to 75% of patients and improvement in another 15% to 21% (Chen and Ball, 1991; Hori et al., 2009; Lee et al., 2014; Padmore et al., 1996; Siu et al., 2007). Results are better in patients with a palpable area of tenderness, area of abnormality on ultrasound, or a cyst (Calleary et al., 2009; Padmore et al., 1996). Results for specifically postvasectomy pain are mixed and range from 12% to 80% cure rates (Hori et al., 2009; Lee et al., 2011; Lee et al., 2014; Siu et al., 2007; Sweeney et al., 2008). **Better rates are reported in cases with incorporation of the distal portion of the vasectomy site with the epididymectomy specimen** (Hori et al., 2009). This removes perineural inflammation, sperm extravasation, and fibrosis that may contribute to ongoing pain (Nariculam et al., 2007a). The rate for progression to orchiectomy after epididymectomy resulting from persistent pain is reported at 22% (Sweeney et al., 2008) up to 90% (Davis et al., 1990).

Orchiectomy for Chronic Scrotal Pain

The results for orchiectomy for chronic scrotal pain vary from 0 to 75% pain relief and partial improvement in 20% to 43% (Costabile et al., 1991b; Davis et al., 1990; Nariculam et al., 2007b; Yamamoto et al., 1995). Better results for an inguinal approach were noted by Davis than using a scrotal approach, 75% versus 55% complete response (Davis et al., 1990). In 17 patients after inguinal hernia repair, 65% were pain free at an average follow-up of 7 years. Of these, 6 patients were operated on for testicular ischemia. Patients operated on for nociceptive pain resulting from testicular injury such as ischemia have a better response than those operated for neuropathic pain from testicular nerve injury (Ronka et al., 2015).

Orchiectomy performed for persistent pain an average of 13.8 months after microsurgical resulted in a complete pain response in 70% and 30% still on pain medications. Men with bilateral scrotal content pain were at higher risk to develop pain after MDSC (Lipscomb and Williams IV, 2016). Although orchiectomy may be considered the last resort for treatment of scrotal pain, pain may persist, called a phantom pain (Puhse et al., 2010). Treatment of pain that persists after orchiectomy is handled in a manner similar to that described for treating persistent testicular pain after inguinal hernia repair. The genital branch of the genitofemoral nerve at the external ring is identified and neuroma is resected, and the proximal end of the nerve is placed in the pelvis. This has resulted in excellent relief in 8 out of 10 men treated for residual pain after prior orchiectomy at a mean of 17.5 months’ follow-up. The remaining two men reported a good result (Dellon et al., 2014).

An algorithm for the progression of surgical therapy in men with chronic scrotal pain is shown in Fig. 56.8.



Chronic Scrotal Pain
Evaluate for ongoing infection, ischemia, malignancy
Persistent pain
Postvasectomy
Not Postvasectomy
Specific lesion: cyst, varicocele
Reversal by vasovasostomy or epidiymovasostomy
Surgery for specific lesion
Persistent pain
Microsurgical denervation of cord
Epididymectomy for epididymal pain
Orchiectomy (inguinal)
Post hernia repair pain
Resect neuroma of genital branch of the genitofemoral nerve at the external ring

FIG. 56.8 Algorithm for progression of surgical therapy for men with chronic scrotal pain.

Key Points

- Viral orchitis is most commonly caused by the mumps virus.

- For scrotal pain a duplex Doppler ultrasound should be performed to assess for anatomic or congenital abnormality, torsion, or mass.
- Pelvic floor physical therapy should be considered in men with orchalgia and abnormal tone on digital rectal examination.
- Acute epididymitis is more commonly caused by an STD in men younger than 35 and enteric organism in men older than 35.
- For MDSC, three areas that should be addressed are the cremasteric muscle fibers, the perivasal sheath, and the posterior lipomatous tissue.
- The distal vas deferens should be incorporated into the surgical specimen during an epididymectomy for postvasectomy pain syndrome.

Interstitial Cystitis/Bladder Pain Syndrome and Related Disorders

Robert M. Moldwin MD, Philip M. Hanno MD, MPH

A Brief History and Overview

Our current understanding of interstitial cystitis/bladder pain syndrome (IC/BPS) has evolved much from 1876, when Dr. Samuel Gross coined the term *interstitial cystitis*, describing a condition of chronic bladder inflammation of unknown etiology (Gross, 1876). In 1918, Dr. Guy Hunner extended this work in his report of "classical" interstitial cystitis; rare patients presented with bladder pain on filling and the cystoscopic finding of inflamed areas of the bladder wall (Hunner, 1915, 1918). This was later termed *Hunner lesions (HLs)*. Clinical experience over the next 50 years revealed that the vast majority of patients who presented with bladder pain had no evidence of bladder wall abnormality on routine cystoscopic examination. A 1987 National Institutes of Health/National Institute of Diabetes and Digestive and Kidney Diseases (NIH/NIDDK) meeting of "experts" produced a definition of IC with the objective to provide a homogenous population of patients for clinical trials (Gillenwater and Wein, 1988). Many clinicians incorporated these criteria into their practices only to find that they excluded approximately 60% of individuals who would otherwise have been clinically diagnosed with the condition (Hanno et al., 1999). Clearly, our definition needed to broaden, and this needed to be reflected in its nomenclature. Although controversy remains, the term *bladder pain syndrome (BPS)* is currently most commonly used and was selected to meet standards of medical pain taxonomy (Baranowski, et al., 2008). Today, **IC/BPS may be defined clinically as "an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms (LUTS) of more than six weeks duration, in the absence of infection or other identifiable causes"** (Hanno and Dmochowski, 2009). This definition is based on what we now believe to be a heterogeneous syndrome, a form of chronic pelvic pain that spans the gamut of patients to include not only those who present with gross inflammatory disease of the bladder wall but also those who have no visible inflammation but endorse bladder pain and often have multiple nonurologic complaints of pain (Nickel and Moldwin, 2018; Tripp et al., 2012) (Fig. 57.1).

FIG. 57.1 Evolving nomenclature/taxonomy and definitions are associated with a larger and more diverse patient population, all with a similar clinical presentation. The "?" denotes mounting interest to separate "classical IC" (as a disease typified by easily identifiable bladder wall inflammation) from the remainder of "syndromic" patients. *UCPPS,* Urologic chronic pelvic pain syndrome. (Modified from Nickel JC, Moldwin R. FDA BRUDAC 2018 Criteria for Interstitial Cystitis/Bladder Pain Syndrome Clinical Trials: Future Direction for Research. *J Urol* 200[1]:39–42, 2018.)

Difficulties encountered with the development of treatment strategies may be confounded by this heterogeneity, prompting many investigators to suggest that better phenotyping of the patient population may result in better clinical outcomes (Nickel and Moldwin, 2018). As our definition of the condition has broadened, prevalence estimates have increased dramatically. Current population-based studies conservatively estimate 2.1 million men (Suskind, et al., 2013) and 3.3 million women (Berry et al., 2011) in the United States having symptoms consistent with IC/BPS.

Definition, Nomenclature, and Taxonomy

“The beginning of wisdom is the definition of terms.” —Socrates (Nails, 2018)

How we define and what we name a medical condition may have an enormous impact on its diagnosis, its epidemiology, the protocol of clinical trials, recognition by the medical community, the names of patient support groups, and (in many countries) patient insurance coverage and physician reimbursement. Even subtle changes in definition, whether it be the character of pain, the location, its association with voiding or not, or its duration may have a profound effect on many of these parameters. A simple example is that of the International Continence Society's definition of *painful bladder syndrome (PBS)* as “the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology” (Abrams et al., 2002). Simply requiring pain to be suprapubic and linked to bladder filling eliminated 34% of patients who were clinically diagnosed with IC/PBS (Warren et al., 2006). Another example is the study by Berry et al. in which a minor change in definition (high sensitivity vs. high specificity definitions) resulted in a difference of 4.3 million estimated to have symptoms suggestive of the condition (Berry et al. 2011)!

The reader may note that current literature is replete with varied terms including *hypersensitive bladder* (Homma et al., 2009), *painful bladder syndrome/interstitial cystitis (PBS/IC)* (Hanno et al., 2005a), *interstitial cystitis/painful bladder syndrome (IC/PBS)* (Hanno et al., 2005b), and *bladder pain syndrome/interstitial cystitis (BPS/IC)* (Fall et al., 2010). **For purposes of clarity and in accordance with the guidelines of the American Urological Association (AUA), this chapter will default to the terminology of the International Consultation on Incontinence (ICI)—*bladder pain syndrome*—but keeps the term *interstitial cystitis* to facilitate recognition and understanding.**

Mounting evidence suggests that BPS is indeed a syndrome and distinct from those patients presenting with HLs (Abrams et al., 2018; Akiyama et al., 2018; Fall and Peeker, 2013; Han et al., 2018; Hanno et al., 2011, 2013) (see Fig.

57.1). This was a topic highlighted at a recent U.S. Food and Drug Administration (FDA) Bone, Reproductive, and Urologic Drugs Advisory Committee (BRUDAC) meeting. The primary question discussed was whether patients with IC and BPS should be combined in future clinical trials. The question itself implied that IC and BPS are two clinically and pathologically separate conditions. Ultimately by unanimous decision, the committee chose to study the two conditions together primarily *based on symptoms* that are indistinguishable from one another (Nickel and Moldwin, 2018).

Interstitial Cystitis/Bladder Pain Syndrome Research Criteria and Their Influence on Clinical Practice

In an effort to define IC so that patients in different geographic areas and under the care of different physicians could be compared, the NIDDK held a workshop in August 1987 at which consensus criteria were established for the diagnosis of IC (Gillenwater and Wein, 1988). **These criteria were not meant to define the disease, but rather to ensure that groups of patients included in basic and clinical research studies would be relatively comparable.** After pilot studies were carried out to test the criteria, they were revised at another NIDDK workshop 1 year later (Wein et al., 1990) (Box 57.1).

Box 57.1

National Institute of Diabetes and Digestive and Kidney Diseases Diagnostic Criteria for Interstitial Cystitis

To be diagnosed with interstitial cystitis, patients must have either glomerulations on cystoscopic examination or a classic Hunner ulcer, and they must have either pain associated with the bladder or urinary urgency. An examination for glomerulations should be undertaken after distention of the bladder under anesthesia to 80 to 100 cm H_2O for 1 to 2 minutes. The bladder may be distended up to two times before evaluation. The glomerulations must be diffuse—present in at least three quadrants of the bladder—and there must be at least 10 glomerulations per quadrant. The glomerulations must not be along the path of the cystoscope (to eliminate artifact from contact instrumentation). The presence of any one of the following excludes a diagnosis of interstitial cystitis:

1. Bladder capacity of greater than 350 mL on awake cystometry using either a gas or liquid filling medium
2. Absence of an intense urge to void with the bladder filled to 100 mL of gas or 150 mL of liquid filling medium
3. The demonstration of phasic involuntary bladder contractions on cystometry using the fill rate just described
4. Duration of symptoms less than 9 months
5. Absence of nocturia
6. Symptoms relieved by antimicrobial agents, urinary antiseptic agents, anticholinergic agents, or antispasmodic agents
7. A frequency of urination while awake of fewer than eight times per day
8. A diagnosis of bacterial cystitis or prostatitis within a 3-month period
9. Bladder or ureteral calculi
10. Active genital herpes
11. Uterine, cervical, vaginal, or urethral cancer
12. Urethral diverticulum
13. Cyclophosphamide or any type of chemical cystitis
14. Tuberculous cystitis
15. Radiation cystitis
16. Benign or malignant bladder tumors
17. Vaginitis
18. Age younger than 18 years

From Wein AJ, Hanno PM, Gillenwater JY. Interstitial cystitis: an introduction to the problem. In: Hanno PM, Staskin DR, Krane RJ, et al., eds. *Interstitial cystitis*. London: Springer-Verlag; 1990:13–15.

Historical Perspective of Interstitial Cystitis/Bladder Pain Syndrome: Early 1800S to 1970S

IC was recognized as a pathologic entity during the 19th century (Parsons and Parsons, 2004; Meijlink, 2018). Joseph Parrish, a Philadelphia surgeon, described three patients with severe lower urinary tract symptoms (LUTS) in the absence of a bladder stone in an 1836 text and termed the disorder *tic douloureux of the bladder* (Parrish, 1836). Teichman argued that this may represent the first description of IC (Teichman et al., 2000). In 1876, Dr. Samuel Gross, of Jefferson Medical College in Philadelphia used the term *interstitial cystitis* to describe inflammation of the bladder "when all the coats are implicated" (Gross, 1876). Several years later, Dr. Alexander Skene used the term *interstitial cystitis* to describe an inflammation that had "destroyed the mucous membrane partly or wholly and extended to the muscular parietes" (Skene, 1887).

Early in the 20th century, at a New England Section meeting of the AUA, Guy Leroy Hunner, a gynecologist at Johns Hopkins University, reported on eight women with a history of suprapubic pain, frequency, nocturia, and urgency lasting an average of 17 years (Hunner, 1915, 1918). He drew attention to the disease, and the red, bleeding areas he described on the bladder wall came to be called *Hunner ulcers*. As Walsh (1978) observed, this has proved to be unfortunate. In the early part of the 20th century, the very best cystoscopes available gave a poorly defined and ill-lit view of the fundus of the bladder. It is not surprising that when Hunner saw red and bleeding areas high on the bladder wall, he thought they were ulcers. For the next 60 years, urologists would look for ulcers and fail to make the diagnosis in their absence. The disease was thought to be focal, rather than a pancystitis.

Hand (1949) authored the first comprehensive review about the disease, reporting on 223 patients. He noted "small, discrete, submucosal hemorrhages, showing variations in form … dot-like bleeding points … little or no restriction to bladder capacity." Walsh (1978) later coined the term ***glomerulations*** to denote the petechial hemorrhages that Hand had described. Messing and Stamey (1978) took this a step further, declaring that in the correct clinical setting, glomerulations should be considered the "hallmark" of the disease. They felt that

Hunner's ulcers represented a different stage of the condition, implying that a spectrum of disease severity exists that is defined by physical findings.

Unexpectedly, the medical community began to use the NIDDK research criteria to establish a diagnosis in their clinical practice, leading to concerns of underdiagnosing the condition. The specificity of the finding of bladder glomerulations before or after distention came into question (Erickson, 1995; Tomaszewski et al., 2001; Waxman et al., 1998). Many patients who presented with IC symptoms had no evidence of glomerulations under anesthesia (Al Hadithi et al., 2002; Awad et al., 1992). Even the consistency of finding glomerulations at varying time points had been called to question (Shear and Mayer, 2006).

The multicenter Interstitial Cystitis Data Base (ICDB) study conducted through the NIDDK accumulated data on 424 patients with IC, enrolling patients from May 1993 to December 1995. Entry criteria were much more symptom driven than those promulgated for research studies (Simon et al., 1997). Notably, no evidence of HLs or glomerulations was needed for study participation. In an analysis of the defining criteria (Hanno et al., 1999), it appeared the NIDDK research criteria fulfilled their mission. **Fully 90% of expert clinicians agreed that patients diagnosed with IC by those criteria in the ICDB indeed had the disorder. However, 60% of patients deemed to have IC by these experienced clinicians would not have met NIDDK research criteria.** With this dilemma in mind, the European Society for the Study of Interstitial Cystitis (ESSIC) (recently renamed the International Society for the Study of BPS) developed a definition by which patients would be required to meet less stringent criteria: pelvic pain for longer than 6 months; pressure or discomfort perceived to be related to the urinary bladder accompanied by at least one other urinary symptom such as persistent urge to void or frequency; and the exclusion of confusable diseases as the cause of the symptoms (van de Merwe et al., 2008). The broader definition facilitated the diagnosis and treatment in many patients who would otherwise remain undiagnosed (Proaño et al., 2013). Although not mandated, cystoscopy with hydrodistention (CHD) and biopsy was suggested to allow subtyping.

IC/BPS is now viewed not only through the paradigm of a chronic pain syndrome that manifests through bladder-related symptoms, but as a syndrome that may not be a true disease of the bladder alone in many patients (Hanno, 2008). This paradigm is reflected in the ongoing Multi-Disciplinary Approach to the Study of Chronic Pelvic Pain (MAPP) Research Network (https://www.mappnetwork.org/), where the breadth of pelvic pain studied extends to IC/BPS and men afflicted with chronic prostatitis/chronic pelvic pain syndrome, collectively termed *urologic chronic pelvic pain syndrome (UCPPS)*. UCPPS is characterized by chronic pain in the pelvic region or genitalia, often accompanied by urinary frequency and urgency (Clemens et al., 2019; Landis et al., 2014).

Key Points: Bladder Pain Syndrome and Interstitial Cystitis

- *Bladder pain syndrome* is a term developed to meet current standards of pain taxonomy. BPS encompasses patients with pain perceived to be bladder-based associated with urinary urgency or frequency in the absence of other identified causes of symptoms. BPS includes subgroups such as those meeting NIDDK criteria and the smaller subgroup of patients with “classical disease” (HLs).
- The term *interstitial cystitis* is currently wrapped in controversy, as it is not a modern histologic description of the condition, even for those patients who manifest gross inflammatory disease of the bladder. Nevertheless, the term remains beside BPS (as IC/BPS) to facilitate patient care and to acknowledge patient support groups such as the Interstitial Cystitis Association (ICA; www.ichelp.org). Whether the older term *interstitial cystitis* should refer to a distinct subgroup of BPS (i.e., those with HLs) is, as yet, unclear.
- The HL (formerly termed *Hunner ulcer*) is the pathognomonic finding for the “classical form” of IC and represents a minority of the IC/BPS population. HLs are easily identified during office cystoscopy, although bladder distention beyond functional capacity and other imaging strategies have been used to enhance identification (Ueda et al., 2008). There is a lack of consensus as to which pathologic findings, if any, are required for, or even suggestive of, a tissue diagnosis (Hanno et al., 2005a; Tomaszewski et al., 1999, 2001).

Voiding Symptoms and Interstitial Cystitis/Bladder Pain Syndrome

Although bladder pain is the central symptom of IC/BPS and the most frequent reason for seeking health care (Clemens et al., 2018), urinary urgency is also commonly described. The ICS definition of urgency as “a *sudden* compelling desire to pass urine, which is difficult to defer” (Abrams et al., 2002) has been useful for the diagnosis of overactive bladder (OAB), and its presence in the IC/BPS patient has prompted suggestions that IC/BPS and OAB syndrome may represent a spectrum of bladder hypersensitivity (Homma, 2008; Lai et al., 2014). Nevertheless, qualitative differences in urgency usually exist between OAB and IC/BPS. **As compared with the OAB patient who fears urine loss, IC/BPS patients often describe a compelling need to void centered on mounting (not sudden) pain, pressure, or pelvic discomfort that occurs with filling.**

Urgency is not a symptom that defines IC/BPS. It is a term often poorly defined and comprehended by patients and cannot be used to clearly discriminate between IC/BPS and OAB (Clemens et al., 2011). Studies through the MAPP Network also demonstrate that descriptions of urgency vary independently from pain (Lai et al., 2015), suggesting that these symptoms should be monitored separately. Making matters more complex, the diagnosis of IC/BPS does not preclude coexisting detrusor overactivity (DO). In studies through the NIDDK database, Nigro et al. (1997a) found a 14% incidence of urodynamic DO in the IC/BPS patients, a prevalence probably close to what one might expect in the general population if studied urodynamically (Salavatore et al., 2003).

The downstream effect of urinary urgency would, of course, be low-volume urinary frequency (Abrams, 2005). **Although BPS patients may have significantly higher voiding frequencies, smaller voided volumes, and narrower ranges of voided volume compared with OAB patients** (Kim et al., 2014)**, one cannot distinguish between the two syndromes based on a voiding diary.**

High-tone pelvic floor dysfunction (HTPFD; often termed *hypertonicity of the pelvic floor musculature, nonrelaxing pelvic floor dysfunction, pelvic floor spasm*, or *myalgia of the pelvic floor*) may produce irritative and/or obstructive voiding symptoms and/or pelvic pain (Kuo et al., 2015). **HTPFD has been identified in 70% to 94% of IC/BPS patients either on the basis of urodynamically proven voiding dysfunction** (Butrick et al., 2009) **or reproduction of pelvic pain on examination of the pelvic floor musculature** (Peters et al., 2007, 2008). The clinical diagnostic dilemmas generated by the presence of HTPFD include its ability to generate pain alone or in association with IC/BPS, and the overlap of symptoms between these conditions. The associated irritative symptoms may be confused for OAB. HTPFD may also be responsible for complaints associated with other pain syndromes such as chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) (Shoskes et al., 2008) and vulvodynia (Bornstein et al., 2016) (Fig. 57.2).

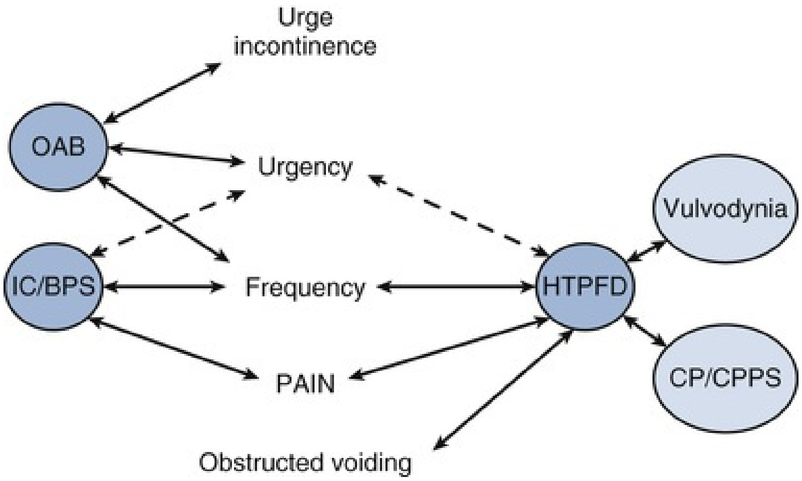

FIG. 57.2 Urinary complaints shared by commonly encountered urological conditions, adding to the complexity of diagnosis. Note that the varied constellation of symptoms associated with pelvic floor dysfunction/spasm may be remarkably similar to those of IC/BPS and OAB. HTPFD may also be associated with other pain syndromes that have been associated with IC/BPS. *CP/CPPS*, Chronic prostatitis/chronic pelvic pain syndrome; *HTPFD,* high-tone pelvic floor dysfunction; *IC/BPS,* interstitial cystitis/bladder pain syndrome; *OAB,* overactive bladder. (Modified from Abrams P, Hanno P, Wein A. Overactive bladder and painful bladder syndrome: there need not be confusion. *Neurourol Urodyn* 24[2]:149–150, 2005.)

Key Points: Lower Urinary Tract Symptoms and the Patient With Interstitial Cystitis/Bladder Pain

Syndrome

- Urgency has been defined as the complaint of a sudden compelling desire to pass urine that is difficult to defer. Fear of incontinence is more consistent with OAB, whereas pressure, pain, or discomfort suggests IC/BPS.
- As compared with the relatively uncommon finding of OAB, HTPFD is present in the majority of IC/BPS patients. This functional disorder may pose a diagnostic challenge as associated LUTS and pelvic pain overlap with IC/BPS.

Epidemiology of Interstitial Cystitis/Bladder Pain Syndrome

Since initial population-based studies of the 1970s to early 1990s, we have seen a significant increase in IC/BPS prevalence estimates, likely a result of a more liberalized definition, one without any specific physical findings needed or biochemical markers available (Nickel, 2018) (Table 57.1). Methodologic differences may also account for much of the variability in prevalence noted among investigations.

Dx, Diagnosis; *F/M,* female/male; *IC/BPS,* interstitial cystitis/bladder pain syndrome.

The relatively low prevalence of IC/BPS reported by Bade et al. (1995) of 8 to 16 of 100,000 might be expected as data were derived from questionnaires completed by urologists, 80% of whom used elevated mast cell counts on bladder biopsy to make the diagnosis. Two symptom-based questionnaire studies by Parsons et al. (2002a) demonstrated the other side of the prevalence spectrum. One survey queried female health care professionals or their spouses attending a lecture by the author, and the other focused on third-year American female medical students (Parsons and Tatsis, 2004). Both studies suggested that IC/BPS prevalence might be as high as 20,000 per 100,000 of the female population. Assessment of male IC/BPS prevalence has been particularly challenging because of clinical similarities between IC/BPS and CP/CPPS (Arora and Shoskes, 2015).

The most sophisticated large-scale, population-based IC/BPS prevalence study to date was conducted by the RAND Corporation and termed the RICE (RAND Interstitial Cystitis Epidemiology) study. With use of a case definition with an 83% specificity, a random sample of 146,231 households was contacted by telephone, and 12,752 women completed the questionnaire; 2.7% met the high-specificity definition of BPS. **The figures correspond to 3.3 million women in the United States 18 years of age or older with symptoms compatible with the diagnosis** (Berry et al., 2011). Prevalence increased with age from 2.21% for 18 to 29 years of age to a high of 3.41% for 50 to 59 years of age and then decreased to 1.70% for 70 to 75 years of age. Of note is that less than 10% of these women had a clinical diagnosis of IC/BPS. When the same methodology was applied to men, the **findings suggested that 1.9% (2.1 million) of adult US males have symptoms of IC/BPS,** higher than the weighted prevalence of chronic prostatitis and CPPS (Suskind et al., 2013). Although these prevalence studies suggest that a high percentage of IC/BPS patients are male, one must note that they were based on symptoms rather than diagnoses. **Investigations based on diagnoses in clinical practice suggest a female-to-male ratio of 5 : 1** (Clemens et al., 2005).

Interstitial Cystitis/Bladder Pain Syndrome in

Children

No studies exist that detail the prevalence of IC/BPS in childhood; however, the condition is considered to be uncommon. On the other hand, children with voiding dysfunction, often associated with disturbances of bowel and pelvic floor behavior, are commonly evaluated in pediatric urology practices (Aguiar and Franco, 2018; Santos et al., 2017). Many of these patients present with varied complaints of pelvic and/or urethral pain that easily can be confused with those of IC/BPS. A recall-based study suggested that adult female IC/BPS patients have a higher prevalence of urinary urgency and recurrent urinary tract infections during childhood than an asymptomatic cohort (Peters et al., 2009). In a recent recall survey, Doiron et al. (2017) also detected a link back to childhood bladder and bowel dysfunction. They found that IC/BPS patients with irritable bowel syndrome (IBS)–like symptoms frequently complained of the need to push for a bowel movement, voided only once or twice daily, and had painful urination during childhood. This coupled with the known high prevalence of HTPFD in the IC/BPS population merits concerns that adult IC/BPS patients may have linked bladder-bowel-pelvic floor dysfunction dating back to childhood (Costantini et al., 2018).

There is a small cohort of children with chronic symptoms of bladder pain, urinary frequency, and sensory urgency in the absence of infection who have been evaluated with urodynamics, cystoscopy, and bladder distention and have findings consistent with the diagnosis of IC/BPS. In a review of 20 such children by Close et al., the median age of **onset was younger than 5 years, and the vast majority of patients had long-term remissions with bladder distention** (Close et al., 1996). This group also emphasized the need to differentiate these patients from those with dysfunctional voiding.

The Epidemiology of Hunner Lesions

One might expect epidemiologic studies related to the classical form of IC/BPS to be straightforward, given that this is a diagnosis primarily based on physical findings. Unfortunately, this has not been the case. The relative rarity of these lesions has hampered patient accrual for the development of longitudinal data. Medical coding strategies often do not distinguish HL patients from those without lesions, thus making even retrospective studies difficult to perform. Most patient populations related to HLs have been derived from tertiary care centers and are, therefore, unlikely to truly reflect general population demographics. Despite these limitations, common epidemiologic threads among studies do exist.

Data regarding the prevalence of HLs in practice range from 3.5% to 56% (Table 57.2), generating an average prevalence among studies of approximately 20%. The vast majority of these data come from clinical practices within tertiary care centers. This selection bias and other concerns, previously detailed, suggest that extrapolation of prevalence data to the general IC/BPS population should be done with caution.

TABLE 57.2

Percentage of Hunner Lesion Patients Within Varied IC/BPS Studies

YEAR	AUTHOR	HL PREVALENCE/TOTAL NUMBER OF IC/BPS PATIENTS
1949	Hand	13%/223
1987a	Holm-Bentzen et al.	3.5%/115
1987	Parsons and Mulholland	28%/75
1993	Koziol et al.	20%/374
1996	Koziol et al.	19.6%/565
1997a	Nigro et al.[a]	11.3%/113
1997	Simon et al.[a]	10.5%/190
1997	Messing et al.[a]	11.3%/150
2001	Forrest et al.[b]	10%/52
2002	Peeker and Fall	56%/231
2004	Forrest and Schmidt[b]	10%/92

2008	Braunstein, et al.	39%/223

2012	Logadottir et al.	55%/393
2013	Killinger et al.	17%/214

[a] Interstitial Cystitis Data Base data. HL prevalence varied from 5.3% to 33.3% between referral centers.

[b] Forrest et al. evaluated only male patients.

HL, Hunner lesion; *IC/BPS,* interstitial cystitis/bladder pain syndrome.

Patients with HLs tend to be older than those without HLs (Table 57.3). This finding was first identified by Hand (1949), who evaluated 223 IC/BPS patients and found that 13% had grade 3 lesions, a description that is consistent with most current HL definitions. He found that these patients were older at symptom onset than those without lesions (average age 41 years vs. 35.5 years, respectively). Female HL patients had a longer interval between symptom onset and diagnosis than non-HL patients (11.5 years vs. 7.5 years, respectively).

2013	Killinger et al.		62[a]		55[a]	

[a] Study did not report the age at diagnosis; rather it only supplied information about the ages of patients at the time of the study.

Koziol et al. (1993) evaluated 374 IC/BPS patients and found that 20.1% had HLs. HL patients had similar age of symptom onset, age of diagnosis, and duration of symptoms to non-HL patients. A subsequent study by the same lead author (1996) evaluating 565 IC/BPS patients (111 with and 454 without HL), however, found the average age of symptom onset to be older in the HL group (46.9 years) than in the non-HL group (40.9 years).

Peeker et al. (2000b) compared 130 HL patients to 101 non-HL patients. They found that HL patients had a higher mean age at symptom onset (55 vs. 30 years of age) and at the time diagnosis (62 vs. 38 years of age).

Rais-Bahrami et al. (2012) analyzed patient demographics, disease characteristics, and symptoms of 268 patients with IC/BPS seen at a tertiary care center between 1990 and 2008 across three age cohorts (<30 years of age, 30 to 60 years of age, and >60 years of age. They found HL in all cohorts, however, there were more HL patients in the older age cohorts (12.0%, 42.0%, and 39.8%, respectively).

The prevalence of HL in young IC/BPS patients is not well established. Hammett et al. (2013) published a case study of a 13-year-old girl with documented HL.

Heredity and Interstitial Cystitis/Bladder Pain

Syndrome

In a pioneering study, Warren et al. (2004) suggested a hereditary aspect to incidence. They found that **adult female first-degree relatives of patients with IC/BPS may have a prevalence of IC/BPS 17 times that found in the general population.** This, together with previously reported evidence showing a greater concordance of IC/BPS among monozygotic than dizygotic twins, suggests but does not prove a genetic susceptibility to IC/BPS that could partially explain the discord in prevalence rates in different populations (Warren et al., 2001, 2004). A recent study using genetic linkage analysis suggested that a genetic variant on chromosome 3 and possibly on chromosomes 1, 4, 9, and 14 contribute to an IC/BPS predisposition (Allen-Brady et al., 2018). The same group examined familial clustering of IC/BPS with 21 associated medical conditions. Diagnoses of myalgia and myositis/unspecified (fibromyalgia syndrome [FMS]) and constipation were found in significant excess in the IC/BPS patients and their first-degree and second-degree relatives. Although environmental factors may account for some of this effect, the excess clustering in more distant relatives suggests that shared genetic factors may account for the coexistence of these conditions (Allen-Brady et al., 2015). Familial clustering has also been reported between IC/BPS and CP/CPPS (Dimitrakov, 2001), a finding not surprising given the clinical overlap between these conditions (Arora and Shoskes, 2015; Moldwin, 2002).

Key Point: Prevalence of Interstitial Cystitis/Bladder Pain Syndrome

- Prevalence studies for IC/BPS show wide variation with a general upsurge over time likely related to a more “liberalized” definition of the condition.
- IC/BPS is uncommon in children, but when present may occur with or without HLs.
- Dysfunctional voiding with bowel and pelvic floor dysfunction may give rise to symptoms similar to IC/BPS and should be considered in the differential diagnosis.
- HL may be identified in approximately 20% of IC/BPS patients in clinical practice.

- Patients with HL are generally older than those without HL.
- Studies, although limited in number, suggest genetic transmission of IC/BPS in some patients.

Natural History, Effects on Quality of Life, and Economic Burden

The natural history of IC/BPS has primarily been assessed through patient recall. Rais-Bahrami et al. found that patients diagnosed at the youngest ages experienced significantly more urinary urgency, frequency, dysuria, dyspareunia, and genital pain. Older patients had a higher incidence of nocturia, urinary incontinence, and HLs (Rais-Bahrami et al., 2012). Patients with mild symptoms at onset appear to show symptom stability at 3 years, whereas those with concomitant chronic fatigue syndrome at symptom onset tend to show symptom progression of IC/BPS over time (Warren et al., 2013). **Prodromal symptoms related to pelvic pain and irritative voiding are often experienced decades before a formal diagnosis.** Urinary frequency without pain was identified in 42% of those patients with prodromal symptoms (Warren et al., 2018). These patients are more likely to have nonbladder syndromes (e.g., FMS) and a poorer prognosis. These findings are consistent with the previously discussed increase in childhood voiding complaints recalled by adult female IC/BPS patients.

Longitudinal studies will often show symptom improvement over the first few weeks simply based on a regression to the mean and an intervention effect (improvement based on the increased follow-up and care) (Propert et al., 2000). This phenomenon was also described by the MAPP Network with the most significant symptom reduction identified between baseline and week 2. A smaller reduction was noted between weeks 2 and 4. This phenomenon reinforces the need for randomized controlled trials (RCTs) and a possible pre-enrollment interval (Stephens-Shields et al., 2016).

Two distinct pain phenotypes have been identified in the IC/BPS patient: those with pelvic pain only and those with "pelvic pain and beyond." Nickel et al. (2015) found that 81% of female IC/BPS patients were afflicted with pain beyond the pelvis and had notably higher levels of sensory type pain, a poorer physical QoL, greater somatic depression, and more sleep disturbance than those with the sole complaint of pelvic pain. Pelvic pain and beyond was also identified in approximately 75% of the MAPP Network's UCPPS patients, a population that also included male CPPS and IC/BPS patients (Clemens et al., 2019). Krieger et al. (2015) reported that 38% of UCPPS patients had at least one nonurologic-associated somatic syndrome (IBS, chronic fatigue syndrome, or FMS). This cohort had more severe symptoms, symptoms of longer duration, and higher rates of depression and anxiety than those with UCPPS only. Collectively, these studies suggest that a significant proportion of IC/BPS patients may have widespread and possibly "centralized" pain that may not respond adequately when only local therapies are applied. The findings also support a role for phenotyping strategies such as UPOINT (Urinary, Psychosocial, Organ specific, Infection, Neurologic/Systemic, Tenderness) for clinical and future research (Nickel et al., 2009b).

Information detailing symptom remission is difficult to capture as the lack of complaints usually obviates the need for office evaluation. The IC database study detailed 35% of IC/BPS patients as having at least one occurrence of symptom remission for greater than 3 months, with 38% of that group having remission for at least 6 months (Simon et al., 1997). **A MAPP Network two-site study found that symptom "flares" occurred in 98% of female UCPPS patients (100% who met IC/BPS criteria).** Flares varied widely in terms of duration (seconds to months), frequency (multiple times per day to once per year or less), symptom type (pain vs. urinary symptoms), and intensity. The most common length of flare was multiple days (87%), with increasing duration of flare associated with greater pelvic pain, urologic symptoms, disruption to participants' activities, and bother (Sutcliffe et al., 2014). A subsequent case-crossover study found sexual activity to be the only consistent factor associated with flare onset. Subpopulations appeared to be triggered by various dietary factors and abdominal exercises (Sutcliffe et al., 2018). These findings support the role to intervene if a trigger for flares is identified, but a rigid plan for flare prevention is not recommended.

As with all forms of chronic pain, IC/BPS is often associated with a decline in mental and physical quality of life (QoL), poor coping skills, anxiety, and depression (Hanno et al., 2005a; Michael et al., 2000; Rothrock et al., 2002, 2003; Vasudevan and Moldwin, 2017). Symptom severity in female IC/BPS patients was an independent predictor of a poorer QoL (body pain, general health, and mental health). A "married" status was associated with both lower symptom severity and improvement in multiple QoL domains (El Khoudary et al., 2009). Furthermore, spousal distraction techniques appear to blunt the effect of pain on the mental QoL.

Sexual dysfunction in female IC/BPS patients may have a profound effect on their physical and mental QoL, underscoring the importance of identifying and ultimately treating this problem when present (Nickel et al., 2007). Catastrophic thinking (defined as believing that the worst may happen and the individual would not be able to tolerate it) was common and associated with greater impairments in various domains, including depressive symptoms, general mental health, social functioning, vitality, and pain (Rothrock et al., 2003). Disability may be partially explained by the impact of negative affect and catastrophizing (Katz et al., 2013). Cognitive behavior therapy approaches that address catastrophizing and mood may serve an important role (Muere et al., 2018).

The symptoms of IC/BPS may affect the patient's ability to adequately function or to function at all in the workplace. IC/BPS patients are six times more likely than individuals in the general population to cut down on work time because of health problems but only half as likely to do so as patients with arthritis (Shea-O'Malley and Sant, 1999). Data collected from the RICE study demonstrated that the *impact* of bladder symptoms on life activities was the most consistent predictor of work outcomes. This suggests an important role for behavioral therapies devoted to improve coping skills and self-management strategies (Beckett et al., 2014).

Abuse and Symptoms

The Boston Area Community Health Survey (BACH) found emotional, sexual, and physical abuse to be a risk factors for symptoms suggestive of IC/BPS (Link and Lutfey, 2007), and this has been borne out in other studies. A Michigan study compared a control group of 464 women with 215 IC/BPS patients and found that 22% of the control group had experienced abuse versus 37% of the patient group (Peters et al., 2007b). A study performed through the Kaiser Permanente database found a 3.8% prevalence of child abuse versus 0.4% in a control population (Clemens et al., 2008b). Those with a history of sexual abuse may have more pain and fewer voiding symptoms (Seth and Teichman, 2008). How reliable these data are is not clear, and it would be wrong to jump to any conclusions about abuse in an individual patient. However, practitioners need to have sensitivity to the possibility of an abusive relationship history in all pain patients, and BPS patients in particular. When patients are found to have multiple diagnoses, the rate of previous abuse also increases, and these patients may need referral for further counseling at a traumatic stress center (Fenton et al., 2008).

Medical Costs

Costs of the disorder are not insignificant and can range from $4000 to $7000 per year, not including lost wages, costs preceding diagnosis, costs of alternative therapies, and costs attributable to misdiagnosis (Clemens et al., 2008a, 2009b). A recent large-scale US-based study was conducted to describe and compare health care utilization, direct costs, and comorbidities for patients with and without IC/BPS during the first year after diagnosis. A diagnosis of IC/BPS was associated with $7223 higher total health care costs than not having IC/BPS, with outpatient costs contributing to 71% of the difference. HL patients used more health care resources as reflected by total health care costs $6895 higher than patients without HL (Tung et al., 2017).

Key Points: Natural History, Effects on Quality of Life, and Economic Burden

- Symptoms tend to fluctuate, with the majority of patients showing no long-term deterioration.
- Two distinct pain phenotypes have been identified in the IC/BPS patient: those with pelvic pain only and those with "pelvic pain and beyond," with the latter group representing over 75% of patients.
- Symptom flares are common and are most commonly experienced for several days. Triggers for flares vary widely among patients.
- Prodromal symptoms related to pelvic pain and irritative voiding are often experienced decades before a formal diagnosis.
- QoL in almost all domains is significantly affected.
- The ability to function effectively or at all in the workplace is affected to a significant degree by coping skills.

Associated Disorders

Multiple medical ailments are associated with IC/BPS. Many of these conditions such as FMS, chronic fatigue syndrome, temporomandibular disorder, and irritable bowel syndrome (IBS) are functional pain disorders that may account for some portion of the 75% to 80% of IC/BPS patients who endorse pain beyond the bladder. Other pain disorders of the pelvis such as HTPFD and vulvodynia are often associated with IC/BPS. Symptoms produced by these other "pain generators" may overlap with those of the bladder, further worsen pain, and complicate management strategies. The association of IC/BPS and other disorders may give clues to underlying etiology and aid in the development of phenotyping strategies.

Based on data developed by the Interstitial Cystitis Association (ICA), a large-scale survey of 6783 individuals diagnosed by their physicians as having IC/BPS studied the prevalence of associated diseases (Alagiri et al., 1997). Data from this group was combined with two smaller studies evaluating the presence of autoimmune disease. These data are compared with a more recent albeit smaller multi-institutional study (205 IC/BPS and 117 age-matched controls) (Nickel et al., 2010b) and presented in Table 57.4. Of note, among studies is the high prevalence of pain syndromes that are believed to have a centralized pain component, that is, FMS, chronic fatigue syndrome, and IBS. **IBS was the most commonly identified associated condition, afflicting over 30% of IC/BPS patients and having the highest prevalence relative to the general population of any functional somatic pain syndrome.** Altered visceral sensation has been implicated in IBS in that these patients experience intestinal pain at intestinal gas volumes that are lower than those that cause pain in healthy persons (Lynn and Friedman, 1993), strikingly similar to the pain on bladder distention in IC. Visceral organ crosstalk presumably mediated through the convergence of sensory neural pathways in the dorsal root ganglion, spinal cord, and/or brain could be responsible for some of this association (Greenwood-Van Meerveld et al., 2015).

TABLE 57.4

Diagnoses Frequently Reported in Interstitial Cystitis/Bladder Pain Syndrome (IC/BPS) Patients

	Van de Merwe, 2003, 2007 Alagiri et al., 1997 Peeker et al., 2003		Nickel et al., 2010
DIAGNOSIS	**PREVALENCE BASED UPON SYMPTOMS (%)**	**PREVALENCE OF CONDITION IN IC/BPS/PREVALENCE OF CONDITION IN GENERAL**	**SELF-REPORTED DIAGNOSIS (%) IC/BPS VS. CONTROL SIGNIFICANT**

		POPULATION	STATISTICAL DIFFERENCES IDENTIFIED FOR ALL DIAGNOSES
Allergy	44	2	
Irritable bowel syndrome	34.3	12	38.6/5.2
Sensitive skin	26.5	2.4	
Vulvodynia	25	3.1[a]	17/0.9
Fibromyalgia	25	7.8	17.7/2.6
Chronic fatigue syndrome	13	1.5	9.5/1.7
Migraine	22.4	1	29.9/11.2
Asthma	9.8	1.6	
Inflammatory bowel disease	8.2	117	
Systemic lupus erythematosus	2.3	46	
Rheumatoid arthritis	4–13	10	
Sjögren syndrome	8.0	15	
Temporomandibular disorder			12/5.2
Low back pain			46.6/18.8

[a] Estimated prevalence for vulvodynia in the general population at the time of study was 15%. A current prevalence estimate is 8% (Harlow et al., 2014). Ratio shown is consistent with updated information.

FMS was also overrepresented in the IC/BPS population**.** This is a painful nonarticular condition predominantly involving muscles; it is the most common cause of chronic, widespread musculoskeletal pain. FMS is typically associated with persistent fatigue, nonrefreshing sleep, and generalized stiffness. Females were once thought to be afflicted ten times more commonly than men (Jacobsen et al., 1993). Paralleling the path of IC/BPS, current epidemiologic findings for FMS suggest that males compose 60% of the population (Wolfe et al., 2018). The association between FMS and IC/BPS is intriguing because both conditions have similar demographic features, modulating factors, associated symptoms, and response to tricyclic compounds (Chelimsky et al., 2012; Clauw et al., 1997).

Sexual pain and dysfunction are commonly encountered in the female IC/BPS patient (Bogart et al., 2011; Rubin and Malphrus, 2018). Some of this pain may be related to **vulvodynia,** a condition defined as vulvar pain of at least 3 months duration without clear identifiable cause, which may have potential associated factors (Bornstein et al., 2016). Studies of vulvodynia prevalence in the IC/BPS patient vary widely from 17% (Nickel et al., 2010b) to almost all patients being affected (Gardella et al., 2011). Furthermore, vulvodynia and IC/BPS share common comorbid conditions including IBS, FMS, and orofacial pain (Nguyen et al., 2013; Reed et al., 2012). The concordance of these noninfectious inflammatory syndromes involving the tissues derived from the embryonic urogenital sinus and the overlap of coexisting functional syndromes argue for a common cause (Fariello and Moldwin, 2015; Fitzpatrick et al., 1993).

Well-defined inflammatory diseases such as Crohn disease, **systemic lupus erythematosus (SLE), Sjögren syndrome (SS),** and rheumatoid arthritis are infrequently seen in the IC/BPS patient, but their relative occurrence (in the few studies available) in this population is astoundingly high. The most frequently encountered of these conditions is IBS/Crohn disease in which prevalence in the IC/BPS population varies between 104 and 117 higher than in the general population (Alagiri et al., 1997). This finding has not been corroborated yet by other investigators.

Several publications have noted an association between IC/BPS and SLE (Boye et al., 1979; de la Serna and Alarcon-Segovia, 1981; Fister, 1938; Meulders et al., 1992; Weisman et al., 1981). Alagiri et al. (1997) suggested a 34 to 46 times higher prevalence of SLE in IC/BPS patients compared with the general population. Complicating studies is the common presentation of bladder symptoms predating an SLE diagnosis (Liberski et al., 2018). The question has always been whether the bladder symptoms represent an association of these two disease processes or rather are a manifestation of lupus involvement of the bladder (Yukawa et al., 2008). This is an important distinction to make as unlike IC/BPS, lupus cystitis may have a much more virulent clinical course with the development of gross inflammatory changes, bladder wall fibrosis, and hydroureteronephrosis (Abelha-Aleixo et al., 2015). Bladder symptoms may also be a consequence of myelopathy with involvement of the sacral cord in a small group of these patients (Sakakibara et al., 2003).

An association has been reported between IC/BPS and SS, an autoimmune exocrinopathy with a female preponderance manifested by dry eyes, dry mouth, and arthritis, but which can also include fever, dryness, and gastrointestinal and lung problems. Van de Merwe et al. (1993) investigated 10 IC patients for the presence of SS. Two patients had both keratoconjunctivitis sicca and focal lymphocytic sialoadenitis, allowing a primary diagnosis of SS. Only two patients had neither finding. He later reported an incidence of 28% of SS in patients with IC (van de Merwe et al., 2003). The incidence of symptoms of IC/BPS in patients with SS has been estimated to be up to 5% (Leppilahti et al., 2003). Patients with SS may have bladder symptoms from DO, and each patient requires careful individual evaluation before a diagnosis of IC/BPS is made (Lee et al., 2011).

HTPFD as identified by tender and hypertonic pelvic floor and associated musculature can be found in approximately 80% of IC/BPS patients (Bassaly et al., 2011). Its clinical importance stems from symptoms that may extensively overlap with IC/BPS, making diagnosis of both conditions more challenging (see Fig. 57.2). The etiology of HTPFD is unknown, but may date back to childhood voiding dysfunction (Doiron et al., 2017). Other etiologic considerations include its development as guarding behavior related to bladder pain. Some authors suggest that cross-talk through viscerosomatic and viscerovisceral neural pathways may play a bidirectional role in the development of IC/BPS and HTPFD (Pezzone et al., 2005). Interestingly, resting state functional MRI demonstrated altered activity and connectivity of pelvic floor sensorimotor cortical control regions in women with IC/BPS (Kilpatrick et al., 2014).

Nickel et al. (2010b) proposed that distinct phenotypes begin to emerge when one examines the epidemiology of IC/BPS and associated medical conditions (Fig. 57.3). The smallest group comprises individuals who only endorse bladder symptoms. Other groups comprise individuals in whom pain is derived from either regional or widespread pain syndromes. More complexity is added, as multiple forms of regional and widespread pain may be present in the IC/BPS patient. Data derived from prior prevalence studies suggest that autoimmune and/or immune-mediated pain may represent another distinct group associated with IC/BPS. Further epidemiologic studies are warranted, because the epidemiology of this disorder may ultimately yield as many clues into cause and treatment as other avenues of research. The heterogeneity of causes and symptoms of IC/BPS suggests that proper clinical phenotyping could foster the development of better treatments for individual phenotypes and more successful treatments for all affected patients (Baranowski et al., 2008; Shoskes et al., 2009).

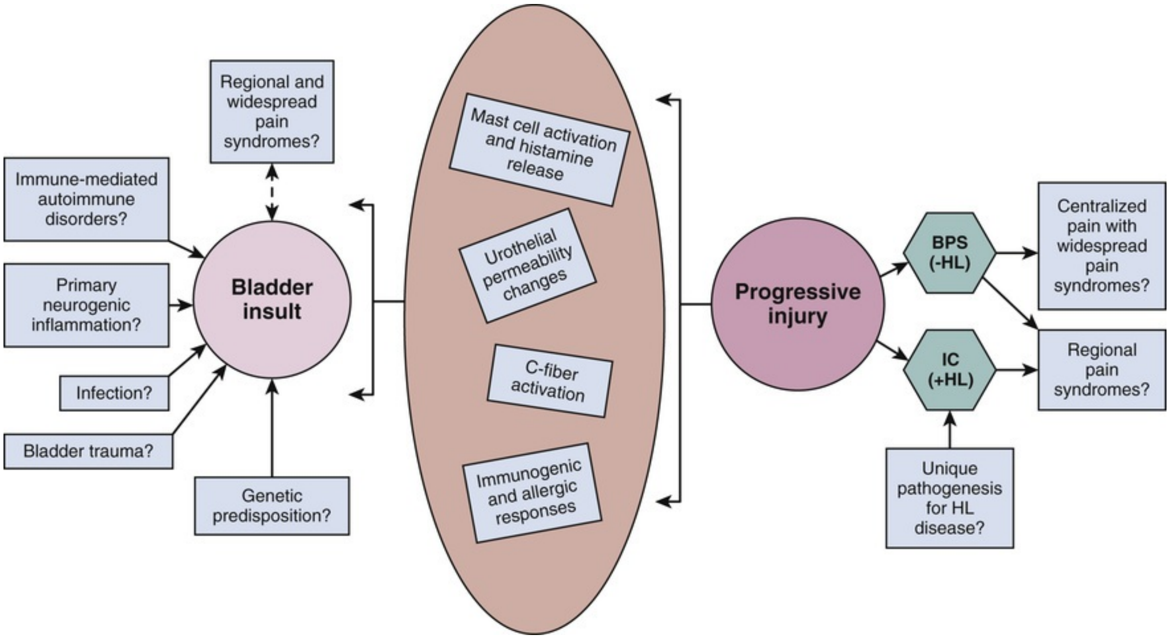
FIG. 57.3 Broad categories of illnesses associated with interstitial cystitis/bladder pain syndrome. *CFS,* Chronic fatigue syndrome; *FMS,* fibromyalgia syndrome; *HTPFD,* high-tone pelvic floor dysfunction; *IBD,* inflammatory bowel disease; *IBS,* irritable bowel syndrome; *RA,* rheumatoid arthritis; *SLE,* systemic lupus erythematosus. (Modified from Nickel JC, Tripp DA, Pontari M, et al. Interstitial cystitis/painful bladder syndrome and associated medical conditions with an emphasis on irritable bowel syndrome, fibromyalgia and chronic fatigue syndrome. *J Urol* 184(4):1358–1363, 2010b.)

Key Points: Associated Disorders

- The bladder-centric patient with IC/BPS is uncommon.
- Regional pain syndromes such as HTPFD, vulvodynia, and IBS may worsen pain. They may also complicate diagnosis because of overlapping symptoms.
- The presence of distinct groups of medical conditions associated with IC/BPS underscores the heterogeneity of the condition, but also suggests that individualized strategies of care will ultimately benefit patients.

Etiology

It is likely that IC/BPS has a multifactorial cause that may act predominantly through one or more pathways, resulting in the typical symptoms (Clemens et al., 2019, Hanno et al., 2013; Nordling et al., 2017; Patnaik et al., 2017) (Fig. 57.4). There is an abundance of theories regarding its pathogenesis, but confirmatory evidence gleaned from clinical practice has proven sparse. Among numerous proposals that have been explored are “leaky epithelium,” mast cell activation, and neurogenic inflammation, or some combination of these and other factors leading to a self-perpetuating process resulting in chronic bladder pain and voiding dysfunction (Elbadawi, 1997). IBS, FMS, chronic fatigue syndrome, and various other chronic pain disorders may precede or follow the development of IC/BPS in some patients (Kim and Chang, 2012), but development of associated syndromes is not inevitable by any means, and their relationship to the cause is currently unknown (Warren et al., 2009). It has been postulated that neural cross-talk in the dorsal root ganglia, in the spinal cord, and at the level of the brain might play a role in the development of chronic pain disorders and their clinical associations through central sensitization (Furuta et al., 2012). This phenomenon may explain the lack of physical findings in many IC/BPS patients and their non-response to local therapies.



Regional and widespread pain syndromes?
Immune-mediated autoimmune disorders?
Primary neurogenic inflammation?
Infection?
Bladder trauma?

BPS (-HL)
IC (+HL)
Unique pathogenesis for HL disease?
Centralized pain with widespread pain syndromes?
Regional pain syndromes?

FIG. 57.4 Multiple etiologic factors may play a role in the development of interstitial cystitis *(IC)*/bladder pain syndrome *(BPS)* symptoms. Current concepts of pathogenesis include its common association with pain beyond the bladder, (regional and widespread). Note the proposed distinction between patients with Hunner lesions (+HL), designated as *IC*, and those without Hunner lesions (–HL), designated as *BPS.*

Animal Models

Until recently, lacking an easily available animal model of the naturally occurring disease, researchers have had to devise animal models to study isolated symptoms of IC/BPS, hoping to uncover the root causes of the symptomatology (Ruggieri et al., 1990). Although animal models can yield clues to cause, all theories must ultimately be tested in humans with the disease. Comparative and translational studies are required if the full potential of findings obtained with animal models is to be realized (Bjorling et al., 2011).

Bullock et al. (1992) reported a mouse model in which bladder inflammation could be induced by the injection of syngeneic bladder antigen. The model demonstrated that a component in the Balb/cAn mouse is capable of inducing a bladder-specific, adoptively transferable, cell-mediated autoimmune response that exhibits many characteristics of clinical IC/BPS, but was difficult to reproduce (Klutke et al., 1997). In another mouse model, immunization of mice with recombinant mouse uroplakin II provoked an autoimmune response sufficient to induce an autoimmune cystitis (Altuntas et al., 2012). Injecting the Bartha strain of pseudorabies virus in the tail of mice causes female gender–specific pelvic pain (Rudick et al., 2012). In a pilot study, a mouse model using a synthetic APF intravesically has yielded histopathologic changes in the mouse similar to findings of IC/BPS patient biopsy specimens (Keay et al., 2012). Vascular endothelial growth factor (VEGF) instillation into the mouse bladder promotes a significant increase in peripheral nerve density with alterations in bladder function and visceral sensitivity (Malykhina et al., 2012).

In a guinea pig model, the instillation of a solution containing a protein to which the animal had been previously immunized resulted in bladder inflammation (Christensen et al., 1990; Kim et al., 1992), as did a rat model of allergic cystitis using a local challenge of ovalbumin in previously sensitized rats (Ahluwalia et al., 1998). Changes in the rat model were dependent on mast cell degranulation and activation of sensory C fibers. Induction of urinary symptoms after 7 days of repeated variate stress has been reported in a rat model (Merrill et

al., 2013).

Ghoniem et al. (1995) studied four female African green monkeys challenged with intravesical acetone (Ghoniem et al., 1995). Not surprisingly, they exhibited symptoms of IC/BPS. Rivas et al. (1997) performed similar experiments using dilute hydrochloric acid in a rat model. A rat model for neurogenic cystitis using pseudorabies virus demonstrated that inflammatory changes in the spinal cord can result in dramatic, neurogenically mediated changes in the bladder (Doggweiler et al., 1998).

The problem with all of these animal models relates to whether or not they mirror the human disease to any great extent. Buffington (2011) has described what appears to be a naturally occurring animal model of IC/BPS. Two-thirds of cats with lower urinary tract disease have sterile urine and no evidence of other urinary tract disorders (Kruger et al., 1991). A portion of these cats experience frequency and urgency of urination, pain, and bladder inflammation (Houpt, 1991). Glomerulations have been observed in the bladders of these animals. GP-51, a glycosaminoglycan (GAG) commonly found in the surface mucin covering the mucosa of the normal human bladder and decreased in IC/BPS, shows a decreased expression in cats with this symptom complex (Press et al., 1995), originally termed *feline urologic syndrome*. Bladder Aδ afferents in these cats are more sensitive to pressure changes than are afferents in normal cats (Roppolo et al., 2005). They also demonstrate an increase in baseline nitric oxide production in smooth muscle and mucosal strips when compared with healthy cats, with evidence of altered mucosal barrier function (Birder et al., 2005).

Buffington et al. (1999) now refers to this disorder as *feline interstitial cystitis (FIC)*. It is associated with urinary urgency, frequency, and pain with sterile urine, bladder mastocytosis, increased histamine excretion, increased bladder permeability, decreased urinary GAG excretion (Buffington et al., 1996), and increased plasma norepinephrine concentrations (Buffington and Pacak, 2001).

Infection

Often, a diagnosis of IC/BPS is made only after a patient has been seen by a number of physicians and treated with antibiotics for presumed urinary tract infection without resolution of symptoms (Held et al., 1990). The symptom complex looks to the patient and physician like an infectious process (Porru et al., 2004). The epidemiology of urinary tract infection and its predominance in women mirror the IC/BPS data (Warren, 1994a). The acute to subacute onset in many patients has fascinated clinicians who often associate an insidious onset with a chronic condition such as IC/BPS.

Reverse logic led some to suspect that antibiotics may be instrumental in causing IC/BPS (Holm-Bentzen et al., 1990). Most patients have been treated with antibiotics once or several times before the diagnosis is made. Numerous antibiotics, primarily in the penicillin family, can induce cystitis (Bracis et al., 1977; Chudwin et al., 1979; Cook et al., 1979; Marx and Alpert, 1984; Møller, 1978), but no evidence has ever been documented that these antibiotics or the supposedly "surface active" nitrofurantoins or tetracyclines have any involvement in pathogenesis (Levin et al., 1988; Ruggieri et al., 1987).

To determine whether there is an infectious cause of IC/BPS, certain procedures are necessary (Warren, 1994b). Not just urine, but bladder epithelium as well must be cultured for appropriate microorganisms, including bacteria, viruses, and fungi. Because some organisms might be culturable yet fastidious, special culture techniques should be used. Because some organisms in urine or tissue might be viable but nonculturable, specific nonculture techniques for discovery and identification should be employed. Most important, the same procedures must be carried out in a control population.

Attempts to show an infectious cause go back to the dawn of the disease, but **the case has never been a strong one** (Duncan and Schaeffer, 1997). Hunner (1915) originally proposed that IC/BPS resulted from chronic bacterial infection of the bladder wall secondary to hematogenous dissemination. Harn proposed a relationship between IC/BPS and streptococcal and poststreptococcal inflammation (Harn et al., 1973). He produced a progressive chronic inflammation in rabbit bladders by injecting small numbers of *Streptococcus pyogenes* in the bladder wall. Studies of *Helicobacter pylori* have failed to demonstrate an association with IC/BPS (Agarwal and Dixon, 2003; Atug et al., 2004; English et al., 1998; Haq et al., 2004). Wilkins found bacteria in catheterized urine specimens and/or bladder biopsy samples in 12 of 20 patients with IC/BPS (Wilkins et al., 1989). However, 8 of the isolates were fastidious bacteria—*Gardnerella vaginalis* and *Lactobacillus* species—and no controls were included in the study. Polyomaviruses have been reported to cause an IC/BPS-like syndrome that responds to cidofovir treatment (Eisen et al., 2009). These viruses are excreted intermittently in the urine of healthy, asymptomatic adults, making diagnosis of a true infection problematic.

Negative studies far outnumber positive ones. Hanash and Pool (1970) performed viral, bacterial, and fungal studies on 30 IC/BPS patients and failed to substantiate an infectious cause. Hedelin et al. (1983) found only 3 of 19 IC/BPS patients to have urine cultures positive for *Ureaplasma urealyticum*, and indirect hemagglutination antibodies to *Mycoplasma hominis* to be no greater than in controls. Potts et al. (2000) cultured *U. urealyticum* in 22 of 48 patients with "chronic urinary symptoms" and had great success in these patients (none of whom had established IC/BPS) with short courses of commonly prescribed antibiotics. Given the history of empirical antibiotics in the vast majority of IC/BPS patients, it is doubtful if this group represents even a small percentage of the IC/BPS-diagnosed population. Nevertheless, it illustrates that IC/BPS is a diagnosis of exclusion; urine culture is critical, and an empirical short course of antibiotics is certainly reasonable if the patient has not already been treated for presumed infection. Empirical doxycycline has been successfully used in this manner (Burkhard et al., 2004).

The development of highly sensitive, rapid, and specific molecular methods of identifying infectious agents by the direct detection of DNA or RNA sequences unique to a particular organism (Naber, 1994) resulted in a flurry of activity into the search for a responsible virus or microorganism. Hampson could find no evidence of mycobacterial involvement in eight cases of IC/BPS with the use of DNA probes (Hampson et al., 1993). Haarala et al. (1996) confirmed an absence of bacterial DNA in the bladder of 11 IC/BPS patients with no documented history of urinary tract infection. Hukkanen et al. (1996) reported an absence of adenovirus and BK virus genomes in urinary bladder biopsy specimens of IC/BPS patients. Domingue et al.'s (1995) provocative findings of the presence of bacterial 16S rRNA genes in bladder biopsy specimens from 29% of IC/BPS patients but not from control bladders and his discovery of 0.22-µm filterable forms in culture of biopsy tissue from 14 of 14 IC/BPS patients and 0 of 15 controls have never been confirmed or repeated.

A preliminary study found a statistically significant increase in urine polymerase chain reaction (PCR) to *Chlamydia pneumoniae* major outer membrane protein gene in patients with IC/BPS as compared with controls (Franke et al., 1999). Other studies have shown that similar percentages of both IC/BPS and control patient populations have nonculturable bacteria in the bladder on the basis of PCR studies of bladder biopsy specimens (Heritz et al., 1997; Keay et al., 1998a). The spirochete *Borrelia burgdorferi* has been found in bladder biopsy specimens and urine of patients with Lyme disease and can cause frequency, urgency, and nocturia. DNA studies have failed to show a role for *Borrelia* in IC/BPS (Haarala et al., 2000). A study using high-throughput sequencing analysis of urine microbiota in IC/BPS patients compared with healthy females showed a reduced microbial diversity and richness accompanied by a higher abundance of the bacterial genus *Lactobacillus* in the IC/BPS group (Siddiqui et al., 2012).

The role of infection in the pathogenesis of IC/BPS remains a mystery. **At this time, there are few data to support the role of an infectious cause,** but investigators keep returning to an infectious theory. Insights into the mechanisms by which bacteria adhere, grow, and persist in association with host tissue and form intracellular pods capable of subverting host defense mechanisms and allowing replication within epithelial cells lay the foundation for a possible role of infection in initiating the IC/BPS pathologic cascade (Kau et al., 2005). The University of Maryland group proposed a model of IC/BPS in which bladder epithelial damage such as that caused by bacterial cystitis may be the first step leading to a low-level inflammatory response (Keay and Warren, 1998). Domingue wrote, “It is logical to suggest that even if organisms are not causative agents, their presence may lead to immune and host-cell responses that could initiate or exacerbate an inflammatory state” (Domingue et al., 1997). In a case-control study, premenopausal women with a history of recurrent urinary tract infections had significantly greater urinary frequency, lower average voided volume, and a lower threshold of bladder sensitivity than controls (Arya et al., 2012).

If infection does play a role, it would be predicted that appropriate treatments to minimize microbial presence in the tissue would significantly improve the morbidity associated with IC/BPS. Durier's (1992) incredible series purporting to cure 27 of 27 IC/BPS patients with the use of up to five sequential antibiotics covering the anaerobic spectrum has never been duplicated. Warren et al.’s (2000) prospective, double-blind, placebo-controlled, randomized trial of 50 patients may well prove the end of long-term empirical antibiotic treatment in established IC/BPS. Eighteen weeks of placebo or antibiotics (sequential doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin, and ciprofloxacin for 3 weeks each) were administered. Most patients guessed the arm to which they were assigned. Of the 25 patients in the active arm, 80% had new nonurinary symptoms perceived as side effects. There was minimal improvement in some patients associated with the active arm, but the conclusion that intensive antibiotics do not represent a major advance in therapy for IC/BPS seems well justified.

Although the concept that a urinary tract infection may trigger IC/BPS in some patients is appealing (Elbadawi, 1997; Elgavish et al., 1995), **it is unlikely that active infection is involved in the ongoing pathologic process or that antibiotics have a role in treatment.**

Autoimmunity and Inflammation

Immune and neuroimmune mechanisms may have an important role in the pathogenesis of IC/BPS. Excessive release of sensory nerve neurotransmitters and mast cell inflammatory mediators is thought by some to be responsible for the development and propagation of symptoms (Luo, 2005). Inflammation results in altered nerve growth factor content of the bladder and morphologic changes in sensory and motor neurons innervating the bladder. Inhibition of nerve growth factor with a monoclonal antibody showed preliminary efficacy in amelioration of IC/BPS symptoms in phase II studies (Evans et al., 2011). Neuroplasticity may be a possible explanation for the association of bladder inflammation with long-term symptoms and pain after inflammation has subsided (Dupont et al., 2001). Up to one-third of IC/BPS patients may have an acute urinary tract infection that immediately precedes the onset of chronic symptoms (Warren et al., 2008). However, abnormal differentiation in the urothelium with a loss of barrier function markers and altered differentiation markers may be independent and occur independently of inflammation (Hauser et al., 2008).

The role of inflammation may stem from inflammation originating in organs other than the bladder. Pain syndromes such as IBS and IC/BPS, which are associated with visceral hyperalgesia, are often comorbid with endometriosis and chronic pelvic pain. Tirlapur concluded that in women with chronic pelvic pain, the mean prevalence of IC/BPS is 61%, the mean prevalence of endometriosis is 70%, and the two problems coexist in 48% of this population (Tirlapur et al., 2013a). One of the possible explanations for this phenomenon is viscerovisceral cross-sensitization, in which increased nociceptive input from an inflamed pelvic organ sensitizes neurons that receive convergent input to the same dorsal root ganglion from an unaffected visceral organ. Visceral sensory integration in the dorsal root ganglia has been demonstrated in a rodent model and may underlie the observed comorbidity of female pelvic pain syndromes (Li et al., 2008).

For many years, the possibility that IC/BPS may represent some type of autoimmune disorder has been considered. Narrowly defined, autoimmune diseases are clinical syndromes caused by the activation of T cells, B cells, or both, in the absence of an ongoing infection or other discernible cause (Davidson and Diamond, 2001). To establish a disease as autoimmune, three types of evidence can be marshaled: (1) direct evidence from transfer of pathogenic antibody or pathogenic T cells; (2) indirect evidence based on reproduction of the autoimmune disease in experimental animals; and (3) circumstantial evidence from clinical clues (Rose and Bona, 1993). Circumstantial evidence would include (1) association with other autoimmune diseases in the same individual or same family; (2) lymphocytic infiltration of a target organ; (3) statistical association with a particular major histocompatibility complex haplotype; and (4) favorable response to immunosuppression.

Circumstantial evidence by itself cannot define an autoimmune disease, and **at this point the case for autoimmunity in IC/BPS is far from clear.** Three different possibilities exist: (1) IC/BPS is caused by a direct autoimmune attack on the bladder; (2) some of the autoimmune symptoms and pathology of IC/BPS arise indirectly as a result of tissue destruction and inflammation from other causes; and (3) autoimmune phenomena in IC/BPS patients are coincident and unrelated to the disease (Ochs, 1997).

Silk found bladder antibodies in 9 of 20 IC/BPS patients and none in 35 pathologic or normal control patients (Silk, 1970). Gordon found antibladder antibodies present in biopsy specimens from 6 of 8 IC/BPS patients and in 3 of 5 control patients (Gordon et al., 1973). No control patient demonstrated antibodies in the muscle, whereas 3 of 5 IC/BPS patients with muscle in the biopsy specimen did. Jokinen looked at sera from 33 IC/BPS patients and found 28 with an antinuclear antibody (ANA) titer of 1 : 10 or greater, but no bladder-specific antibodies were detected with immunofluorescence. There was poor correlation between ANA titers and symptom severity (Jokinen et al., 1972). He noted that elevated antibody titers against cell nuclei and crude kidney homogenate decreased within 12 months after cystectomy in three IC/BPS patients (Jokinen et al., 1973). All of this provided hints that IC/BPS could fall into the autoimmune group of diseases.

Oravisto (1980) summarized the world literature on this idea in 1980, concluding that the chronic course of disease, the absence of infection, the pathologic findings, the occurrence of ANAs, and the reported responses to steroids at that time provided strong circumstantial evidence of autoimmunity. He discounted the paucity of activated lymphocytes, which speaks against an autoimmune process. Studies on autoantibodies in IC/BPS have shown that these mainly consist of ANAs (Jokinen et al., 1972), similar to the autoantibody profiles in some systemic diseases such as SS, well known to be of autoimmune origin (Leppilahti et al., 2003; Tan, 1989). Mattila (1982) presented evidence of immune deposits in the bladder vascular walls in 33 of 47 IC/BPS patients. Studying sera from 41 patients with IC/BPS, he concluded that the classical pathway activation of the complement system was involved, supporting the possibility that a chronic local immunologic process was indeed occurring (Mattila et al., 1983). The autoantibodies tested were found to be directed against cytoskeletal intermediate filaments. As the autoantibodies have to gain access to intracellular structures to cause in vivo deposits, primary tissue injury of unknown cause has to be postulated (Mattila and Linder, 1984).

Anderson et al. (1989) studied 26 patients with IC/BPS and compared them with a control group of similar age and sex with other urologic complaints. They performed a standard autoimmune profile and looked for specific antibodies to normal human bladder in the serum. In this study, 65% of IC/BPS patients and 36% of controls demonstrated non–organ-specific antibodies; 40% of IC/BPS patients had ANAs; and 75% of IC/BPS patients and 40% of controls had antibladder antibodies present in the serum. There was no increase in immunoglobulin deposition in the bladder epithelium in IC/BPS patients versus controls. Although IC/BPS patients demonstrated a nonspecific increase in antibody formation, this was not significantly different from a similar group of other urologic patients. The lack of specificity indicates the immunologic findings are likely secondary to inflammation rather than a primary cause.

In a study looking for active immune cellular deposition in IC/BPS patients, no statistically significant difference between controls and IC/BPS patients was identified (Harrington et al., 1990). In contrast, the IC/BPS with HL group had focal sheets of plasma cells, aggregates of T cells, B-cell nodules, a decreased or normal helper-to-suppressor cell ratio, and suppressor cytotoxic cells in germinal centers. Flow cytometry analysis of peripheral blood lymphocyte subsets showed an increased number of secretory Ig-positive B cells and activated lymphocytes in the non-HL group, and increased numbers of secretory Ig-positive cells and activated lymphocytes in the HL group. These results may suggest a partial role for an immune mechanism in IC/BPS. Gamper et al. (2013) found elevated urinary antibody concentrations in patients with HLs. Erickson et al. (1997a) noted a major difference in inflammatory cell types and clinical features in IC/BPS patients with severe inflammation, suggesting two different patient groups with two different underlying pathophysiologies.

Christmas (1994) reported increased numbers of CD4+ and CD8+ T cells in bladder biopsy specimens from patients with IC/BPS and bacterial cystitis as compared with controls. These T cells were present in the urothelium and submucosa but not in the detrusor. Control bladder tissue demonstrated only CD8 cells in the urothelium and both CD4+ and CD8+ cells in the submucosa. The number of plasma cells was significantly greater in IC patients than in normal controls and controls with bacterial cystitis.

MacDermott et al. (1991b) found a normal distribution of peripheral blood lymphocytes in IC/BPS patients, a finding not supportive of an autoimmune mechanism in the disease (MacDermott et al., 1991b). The lamina propria showed a predominance of CD4 lymphocytes (helper T cells) over CD8 cells in both IC/BPS and other cystitis patients. The same pattern was seen in the epithelium of patients with bacterial or mechanical cystitis, but patients with IC/BPS had a predominance of CD8 lymphocytes in the urothelium—identical to controls. The findings suggest that the urothelium is not involved in the inflammatory reaction, as is the lamina propria, making the urothelium an unlikely source for the initiating factor.

Miller et al. (1992) investigated the function of peripheral blood lymphocytes from non-HL IC/BPS patients, testing the proliferative response and cytokine production of T cells to nonspecific mitogenic stimulation and the proliferative response of T cells to urine components. Proliferation and cytokine production after mitogen stimulation were the same for controls and IC/BPS patients. Moreover, no immunologic response to IC/BPS urine by autologous peripheral blood lymphocytes in vitro assays was observed. These findings cast doubt on theories, suggesting that IC/BPS is an autoimmune disease.

Numerous inflammatory mediators have been studied with regard to their relation to IC/BPS (Elgebaly et al., 1992; Felsen et al., 1994; Lotz et al., 1994; Steinert et al., 1994; Zuraw et al., 1994). There is a significant elevation of cytokines in IC/BPS bladder tissue when compared with controls (Corcoran et al., 2013) and an increase in urinary nerve growth factor (Liu and Kuo, 2012). The overexpression of genes related to immune and inflammatory responses, including T helper type 1–related chemokines and cytokines such as CXCR3-binding chemokines, may produce potential biomarkers of the disease (Ogawa et al., 2010). Urine sediment may be a substrate for gene expression analysis (Blalock et al., 2012).

Patients with IC/BPS exhibit varying degrees of inflammation that can separate them into clusters (Green et al., 2004; Tomaszewski et al., 2001). Bladder inflammation in IC/BPS is categorized by elevated urinary interleukin-6

(Erickson et al., 1997a) and activation of the kallikrein-kinin system (Rosamilia et al., 1999b). The absence of urinary interleukin-1β in IC/BPS argues against an immunologic or autoimmune cause of the disorder (Martins et al., 1994). Neurogenic inflammation may play a role in the cause, as long-term exposure of afferent nerve terminals to inflammatory mediators can alter ion channels and result in bladder hyperalgesia (Buffington and Wolfe, 1998; Yoshimura and de Groat, 1999). Substance P itself does not seem to be the single initiator of inflammation in the bladder, and its blockade does not protect the bladder from inflammatory responses in animal models (Luber-Narod et al., 1997). Urinary nitric oxide synthase (NOS) activity is known to be elevated in patients with urinary infection and is thought to play a role in the bladder's response to infection and in the inflammatory process that follows infection. The finding that urinary NOS activity is decreased in IC/BPS patients has puzzled researchers but could explain the reduction in functional bladder capacity associated with the disorder (Foster et al., 1997; Smith and Christmas, 1996). However, patients with HLs have high levels of nitric oxide in the bladder. The production of nitric oxide in this entity may occur in different tissue compartments, because there is strong immunoreactivity for both inducible nitric oxide synthase (iNOS) in the urothelium and within the inflammatory infiltrates in the lamina propria of these patients (Logadottir et al., 2013).

Urothelial cell activation in IC/BPS may result in aberrant immune responses and immune activation within the bladder wall (Liebert et al., 1993) that could relate to pathogenesis of the disease but might not reflect the initiating cause (Ochs et al., 1994). It has been proposed that inflammatory and/or immune responses in IC/BPS could be exacerbated by persistent activation of nuclear factor-κB (NF-κB) (Abdel-Mageed, 2003; Abdel-Mageed and Ghoniem, 1998). Angiogenic factors such as platelet-derived endothelial cell growth factor/thymidine phosphorylase and transforming growth factor-β may be involved in the inflammatory process to induce painful symptoms in patients with IC/BPS or bladder carcinoma (Ueda et al., 2002).

The exact role of autoimmunity in IC/BPS remains controversial (Ochs, 1997). Suplatast tosilate, an immunoregulator, has shown efficacy in a small, uncontrolled IC/BPS study in which improvements in symptoms and bladder capacity were correlated with changes in autoimmune parameters (Ueda et al., 2000). **Although the immune system remains a target for therapy, no clear indication of a primary role for autoimmunity as the cause of IC/BPS has been observed** (Liebert and Sant, 1997).

Key Points: Autoimmunity and Inflammation

- Neuroplasticity may be a possible explanation for the association of bladder inflammation with long-term symptoms and pain after inflammation has subsided.
- Abnormal differentiation in the urothelium with a loss of barrier markers and altered differentiation markers may be independent and may occur independently of inflammation.
- Visceral sensory integration may result in inflammation originating in organs other than the bladder causing symptoms identified with IC/BPS.

Mast Cell Involvement

Although mast cells are thought of primarily in the context of allergic disorders and certain acute inflammatory responses, these cells have also been implicated in biologic responses as diverse as angiogenesis and wound healing, bone remodeling, peptic ulcer disease, atherosclerosis, and reactions to neoplasms (Galli, 1993). Mast cells remain one of the most enigmatic cells in the body. They secrete significant amounts of numerous proinflammatory mediators that contribute to a number of chronic inflammatory conditions, including stress-induced intestinal ulceration, rheumatoid arthritis, scleroderma, and Crohn disease. They have been described even among the lowest order of animals, having been discovered in the frog mesentery over 100 years ago. Their raison d'être may be the initiation and coordination of the host's inflammatory and immune responses against microbial pathogens (Abraham and Malaviya, 1997). They have been implicated in a range of neuroinflammatory diseases, especially those worsened by stress (Theoharides, 2004; Theoharides and Cochrane, 2004). These include multiple sclerosis, migraines, inflammatory arthritis, atopic dermatitis, coronary inflammation, IBS, and IC/BPS. They may be activated through their Fc receptors by immunoglobulins other than IgE, and by anaphylatoxins, neuropeptides, and cytokines, to secrete mediators selectively without overt degranulation.

Mast cells have frequently been reported to be associated with IC/BPS, both as a pathogenetic mechanism and as a pathognomonic marker (Bhone et al., 1962; Hofmeister et al., 1997; Larsen et al., 1982; Simmons, 1961; Smith and Dehner, 1972). The association of bladder mastocytosis, IC/BPS, and IBS

(Pang et al., 1996) and chronic urticaria (Sant et al., 1997) is intriguing. Evidence of their importance is mounting, suggesting that **they may serve as the final common pathway through which the symptomatic condition is expressed. Mast cells produce, among other compounds, histamine. Histamine release in tissue causes pain, hyperemia, and fibrosis, all notable features of IC/BPS.**

Simmons was first to suggest mast cells as a cause of IC/BPS (Simmons, 1961). Contribution of mast cells to the cellular infiltrate in IC/BPS has been shown to vary from about 20% in non-HL IC/BPS patients to 65% in HL patients (Enerback et al., 1989; Sant et al., 1988). Mast cells participate in allergic reactions (hypersensitivity—type I) during which IgE antibody is synthesized in response to specific antigens. IgE binds to mast cell receptors, and antigen binds to the IgE, leading to degranulation (Lagunoff et al., 1983). Other triggers of mast cell secretion include acetylcholine, anaphylatoxins, cationic peptides such as substance P, chemicals, contrast, cytokines, opioids, antihistamines, exercise, hormones, viruses, and bacterial toxins (Sant and Theoharides, 1994). Mast cells promote infiltration of neutrophils, T and B lymphocytes, monocytes, and eosinophils. T lymphocytes secrete substances capable of activating mast cells, thus perpetuating the cycle of inflammation (Kaplan et al., 1985).

Since the presence of mast cells within the bladder wall was first recognized (Simmons and Bunce, 1958), numerous investigators have tried to determine whether there is an increase in the number of mast cells in the bladder of patients with IC/BPS, or differences in their location or functional state (Christmas and Rode, 1991; Fall et al., 1987; Feltis et al., 1987; Kastrup et al., 1983; Larsen et al., 1982; Lynes et al., 1987). An increase in urothelial mast cells appears to be part of the generalized inflammatory cell reaction regardless of cause, and not a specific feature of IC/BPS, whereas the presence of increased numbers of mast cells in the detrusor is more specific for IC/BPS. However, one study did report detrusor mastocytosis in 64% of IC/BPS patients and 80% of a control group with other urologic disease, with no statistically significant difference between the mean number of detrusor mast cells in the two groups (Hanno et al., 1990).

Aldenborg reported that mast cells are found predominantly in the detrusor muscle in patients with classic IC/BPS (Aldenborg et al., 1986), but there is also a secondary population of mast cells in the lamina propria and the bladder epithelium, with staining characteristics distinct from those in the detrusor. None of these epithelial mast cells were found in controls. These findings were interpreted to indicate a transepithelial migration of mast cells in patients with IC/BPS. This second population of mast cells does not appear to be involved in the non-HL type of IC/BPS (Aldenborg et al., 1989). This mucosal population of mast cells can also differ from the mast cells found in deeper tissues in physiologic responses and release of secretory products (Sant, 1991). The “mucosal mast cells” are susceptible to aldehyde fixation and require special fixation and staining techniques for proper demonstration. Detrusor mast cells are not susceptible to fixation techniques. Recent studies have shown that although all human mast cells contain the proteinase tryptase, there is a population of mast cells that also contain the proteinase chymase. The mast cell expansion in IC/BPS involves both types (Yamada et al., 2000). Mast cell activation is far more pronounced in the ulcerative form, which in addition displays prominent inflammation, in contrast with non HL IC/BPS, in which it is sparse. Thus, the basic pathologic processes may differ (Peeker et al., 2000b). Because activated mast cells lose their histologically identifiable granules once degranulation has occurred, estimates of mast cell density using standard histologic techniques may underestimate mast cell numbers (Sant and Theoharides, 1994).

Electron microscopy has confirmed that mast cells in IC/BPS are more likely to be degranulated or activated than those found in other conditions (Larsen et al., 1982; Theoharides and Sant, 1991; Theoharides et al., 1995). In at least a subpopulation of IC/BPS patients, this may be explained by increased stimulation of mast cells by stem cell factor (Pang et al., 1998). Chronic exposure of detrusor muscle to histamine in IC/BPS patients is suggested by the finding that there is an impairment of the direct contractile response to histamine in detrusor muscle affected by IC/BPS in comparison with control detrusor, suggesting a receptor desensitization (Palea et al., 1993). The clinical relationship between an increased number of mast cells and symptoms of IC/BPS has not been definitively established. Some studies have found no correlation (Dondore et al., 1996; Holm-Bentzen et al., 1987a; Lynes et al., 1987). Although mast cell infiltration in intestinal segments used for augmentation has been associated with pain and failure of the procedure (Kisman et al., 1991), other researchers have shown that mast cell infiltration in intestine used in the urinary tract is the norm and not pathologic (MacDermott et al., 1990).

Many of the substances that have been shown to induce mast cell secretion are released from neurons that innervate the organ containing the mast cells

(Christmas et al., 1990). The capsaicin-sensitive sensory neurons that innervate the bladder are thought to have a dual “sensory-efferent” function, in which an axon reflex-induced release of neuropeptides results in local inflammation (Barbanti et al., 1993; Foreman, 1987). Hand (1949) reported an increase in the submucosal nerve density in IC/BPS, a phenomenon confirmed by Christmas et al. (1990), who showed an increase in nerve fiber proliferation in patients with IC/BPS but not in patients with bacterial or lupus cystitis. Increased innervation by nerves releasing substances affecting mast cells could lead to increased mast cell secretion. Among these substances is acetylcholine. Mast cells can be stimulated by cholinergic agonists to secrete serotonin (Theoharides and Sant, 1991). Substance P–containing fibers have been found to be increased in bladders from IC/BPS patients and are found adjacent to mast cells (Pang et al., 1995b). In mice, mast cells modulate the inflammatory response of the bladder to substance P and to *Escherichia coli* lipopolysaccharide (Bjorling et al., 1999).

An increase in adrenergic but not cholinergic nerves in IC/BPS patients as compared with controls has been reported (Hohenfellner et al., 1992). Hohenfellner et al. also found increased numbers of neurons staining for vasoactive intestinal polypeptide and neuropeptide Y (NPY), both of which are associated with sympathetic nerves. Studies in rats have revealed that psychological stress can activate bladder mast cells via the action of sensory neuropeptides (Alexacos et al., 1999; Spanos et al., 1997). Diurnal cortical variations have been associated with symptom levels in IC/BPS (Lutgendorf et al., 2002), and the mast cell may represent a pathway for stress to be reflected in bladder symptomatology.

Mast cells can alter their environment by regulating tissue gene expression (Saban et al., 2001). The finding of increased synthesis of urinary leukotriene E_4 in patients with IC/BPS and detrusor mastocytosis when compared with healthy controls suggests that cysteinyl-containing leukotrienes are involved in the inflammatory reaction observed in the urinary bladder of patients with IC/BPS and may be produced from tissue mast cells in the bladder wall, or macrophages (Bouchelouche et al., 2001a).

Could mast cell products be useful in diagnosing IC/BPS? They are not specific for IC/BPS and are increased in bladder carcinoma (Serel et al., 2004). Elevated histamine levels have been found in bladder biopsy specimens from IC/BPS patients (Enerback et al., 1989; Kastrup et al., 1983; Lynes et al., 1987) and from bladder washings (Lundeberg et al., 1993). Holm-Bentzen et al. (1987b) reported a significantly elevated urinary excretion of 1,4-

methylimidazole acetic acid, the major metabolite of histamine. Others have found no differences between IC/BPS and controls in random spot tests of urinary histamine (Yun et al., 1992). Levels were elevated after hydrodistention in IC/BPS patients but not in controls—a possible consequence of hydrodistention and resultant mast cell degranulation. El Mansoury et al. (1994) found increased methylhistamine, a histamine metabolite, in spot and 24-hour urine samples from IC/BPS patients as compared with controls. Although such an increase could still be interpreted as indicating a systemic rather than a bladder syndrome, subsequent findings of elevated mast cell tryptase in the urine of IC/BPS patients could come only from the bladder (Boucher et al., 1995). Erickson et al. (2004) reported that urine methylhistamine is not useful as an objective marker of response to bladder distention or as a predictor of response to distention or as a substitute for bladder biopsy to determine mast cell counts.

The realization that mast cells are associated with the syndrome of IC/BPS by no means diminishes the other multiple theories of causation. The poor clinical results with antihistamine therapy would argue against their being a primary factor. Their very presence could be related to injury from any of the proposed etiologic theories, and degranulation could likewise reflect a final common pathway resulting in pain and frequency from multiple causes. Rickard and Lagunoff (1995) proposed, based on results with mast cell granules and epithelial cells in tissue culture, that mast cells could contribute to failure of epithelialization of the bladder surface by two potential mechanisms after injury: (1) inhibition of epithelial cell replication, and (2) interference with epithelial cell spreading, thus resulting in the “leaky epithelium” found in some patients. Mast cell activation has been correlated significantly with the apoptotic cell number in IC/BPS bladder tissue (Shie and Kuo, 2011). Mast cells may actually be the mediator through which female hormones play a role, accounting for the 10 : 1 female-to-male preponderance of the disease (Bjorling and Wang, 2001; Pang et al., 1995a; Patra et al., 1995; Vliagoftis et al., 1992). Estradiol augments the secretion of mast cell histamine in response to substance P. It has been proposed that the symptoms of IC/BPS may depend on an imbalance between the relative number of estrogen receptors and progesterone receptors on bladder mast cells (Letourneau et al., 1996).

To summarize, much important IC/BPS research has centered on the mast cell. These cells are strategically localized in the urinary bladder close to blood vessels, lymphatics, nerves, and detrusor smooth muscle (Saban et al., 1997). **Studies to date strongly suggest that IC/BPS is a syndrome with neural,**

immune, and endocrine components in which activated mast cells play a central, although not primary, pathogenetic role in many patients (Elbadawi and Light, 1996; Filippou et al., 1999). Studies in a mast cell–deficient mouse model demonstrate that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and tumor necrosis factor (TNF), respectively, suggesting that pain is independent of pathology and inflammation, and histamine receptors may represent direct therapeutic targets for pain in IC/BPS (Rudick et al., 2008).

Key Points: Mast Cells and Histamine

- Mast cells may be a pathognomonic marker for IC/BPS and also represent a pathogenetic mechanism of the syndrome. They could serve as a final common pathway through which the symptomatic condition is expressed.
- Histamine, produced by mast cells, may cause pain, hyperemia, and fibrosis, all notable features of IC/BPS.

Bladder Glycosaminoglycan Layer and Epithelial Permeability

Until the early 1970s, most investigators thought that the major barrier to free flow of urinary constituents was at the level of the epithelial cells. Tight junctions between urothelial cells, specialized “umbrella cells” lining the surface, and direct bactericidal activity of the vesical mucosa were thought to be capable of defense of the internal milieu from bacteria, molecules, and ions in the urine (Ratliff et al., 1994). Staehelin et al. (1972) proposed that lipid and other hydrophobically bonded materials were important in any barrier to permeability in the luminal membrane because permeants leaked through the interplaque regions if the particles alone limited transport. It has been shown that inflammation of the underlying muscle and lamina propria can disrupt the bladder permeability barrier by damaging tight junctions and apical membranes and causing sloughing of epithelial cells. Leakage of urinary constituents through the damaged epithelium may then exacerbate the inflammation in the underlying tissues (Lavelle et al., 1998, 2000). Early investigators, attempting to find a urothelial defect responsible for symptoms, found remarkable similarities of epithelial cell and glycocalyx ultrastructure between IC/BPS and control specimens (Collan et al., 1976; Dixon et al., 1986). Anderstrom et al. (1989) saw no surface characteristics specific for IC/BPS, but believed that the mucin layer covering the urothelial cells seemed reduced in IC/BPS compared with controls, a fact disputed by Nickel et al. (1993) in a very elegant paper. Elbadawi and Light (1996) observed ultrastructural changes sufficiently distinctive to be diagnostic in specimens submitted for pathologic confirmation of IC/BPS-HL. Marked edema of various tissue elements and cells appeared to be a common denominator of many observed changes. The wide-ranging discussion of the etiology of IC/BPS in this paper is fascinating, but the pathologic findings are potentially marred by the methodology, in that specimens were obtained after diagnostic hydrodistention (Elbadawi,1997).

It was Parsons who hypothesized and popularized the **concept that IC/BPS in a subset of patients is the result of some defect in the epithelial permeability barrier of the bladder surface GAGs** (Parsons and Hurst, 1990). The major classes of GAGs include hyaluronic acid, heparin sulfate, heparin, chondroitin 4-sulfate and chondroitin 6-sulfate, dermatan sulfate, and keratan sulfate. These carbohydrate chains, coupled to protein cores, produce a diverse class of macromolecules, the proteoglycans (Trelstad, 1985). GAGs exist as a continuous layer on the bladder urothelium (Cornish et al., 1990; Dixon et al., 1986). Except heparin, all the other types of GAGs have been found on the bladder surface (Ruoslahti, 1988). **The GAG layer functions as a permeability and antiadherence barrier. When impaired, its functions can be duplicated by exogenous GAG** (Hanno et al., 1978a, 1978b). In the absence of this protective layer in the urinary bladder, its susceptibility to infection would increase, and the production of nitric oxide in the urothelial cells and of substance P in the intraepithelial afferent C-fiber terminals increases. Consequently, the permeability of both the urothelium and the blood vessels in the mucous membrane increases, and the blood flow slows as a result of vasodilatation (Hohlbrugger, 1999).

Parsons and Hurst reported a lower excretion of urinary uronic acid and GAGs in IC/BPS patients than in normal volunteers and hypothesized that a leaky transitional epithelium might be absorbing these substances to its surface (Parsons and Hurst, 1990). The data are interesting in that one might expect urinary GAG to increase with injury to the bladder and decrease with resolution (Uehling et al., 1988). Buzzega et al. (2012) noted a significant increase in total urinary hexosamines and in particular in glucosamine belonging to urinary heparin sulfate in IC/BPS patients compared with controls. The San Diego group (Lilly and Parsons, 1990; Parsons et al., 1990) went on to show experimentally that one can damage the GAG layer with protamine sulfate with resultant back-diffusion of urea through the bladder lumen, and that this urea loss can be prevented with a bladder instillation of exogenous GAG (heparin). By placing a solution of concentrated urea into the bladder of IC/BPS patients and measuring absorption versus controls, Parsons found support for his theory in patients with IC/BPS (Parsons et al., 1991). The rationale of the epithelial permeability school has been nicely summarized in four publications (Hohlbrugger and Riedl, 2000; Hurst et al., 1997; Parsons, 1993, 1994) and provides a comprehensive, if somewhat imperfect, theory of the disorder.

Support for an epithelial abnormality from a different perspective has come from Bushman, who found aneuploid DNA profiles on barbotage specimens from IC/BPS patients that may signal an underlying abnormality of the epithelial cell population in some patients with IC/BPS (Bushman et al., 1994). Wilson et al. (1995) identified a loss of type IV collagen in the urothelial basement membrane in 5 of 11 IC/BPS patients. Hurst et al. (1996) studied bladder biopsy specimens of IC/BPS patients and controls and concluded that there is a deficit of bladder luminal and basal proteoglycans associated with the disorder. The basal abnormality may reflect an altered urothelial differentiation program. In a later study, IC/BPS bladder biopsy specimens showed abnormalities in 24 of 27 patients when examined by immunohistochemical assessment of E-cadherin, ZO-1, uroplakin, and chondroitin sulfate (Slobodov et al., 2004). Erickson et al. (1996) measured a glycoprotein (epitectin) in the urine of IC/BPS patients and found a decrease compared with a control population, although a significant overlap was detected. Buffington and Woodworth (1997) gave 6 IC/BPS patients and 6 controls oral fluorescein dye. IC/BPS patients had higher levels of fluorescein in their plasma and lower urinary excretion of the dye, suggesting altered membrane permeability and increased fluorescein reabsorption in the bladder wall of IC/BPS patients. Erickson et al. (1998) compared urinary levels of hyaluronic acid in IC/BPS patients and controls, reporting higher urinary hyaluronic acid in the patient group, possibly accounted for by leakage of this GAG across the epithelium.

In FIC, the only naturally occurring animal model of the disorder, the urothelium has been shown to have decreased transepithelial resistance and increased water and urea permeability compared with controls in response to hydrodistention (Lavelle et al., 2000). This indicates that barrier function is compromised, which could lead to the sensitization of sensory nerves by irritants from urine crossing into the muscle layer. Bladder strip studies have shown that FIC bladders have significantly more spontaneous Ca^{2+} transients in the mucosal layer than control bladders. Coupled with increased sensitivity of muscarinic receptors in the mucosal layer, these bladders may manifest enhanced smooth muscle spontaneous contractions. This finding could play a contribution in the symptoms of IC/BPS (Ikeda et al., 2009). In fact, human cell culture studies comparing IC/BPS and normal bladder urothelial cells have shown greater sensitivity of IC/BPS bladder urothelial cells to carbachol, suggesting that IC/BPS pathobiology may also include alterations in muscarinic signaling (Gupta et al., 2009). Neuhaus et al. (2012) showed significantly upregulated M_2 (muscarinic), $P2X_1$ and $P2X_2$ (purinergic), and H_1 and H_2 (histaminergic) receptors in the tissue of IC/BPS patients.

Further data for an abnormal surface mucin came from Moskowitz et al. (1994), who studied biopsy specimens from 23 IC patients with regard to the presence of a glycoprotein component of the surface mucin referred to as *GP1* and compared the results with 11 normal controls. Qualitative GP1 changes in a majority of IC/BPS patients were identified. GP1 reactivity was noted in all controls but was absent in 35% of IC/BPS patients and diminished in 61%. This study may provide evidence of an abnormal bladder urothelium, but the effects of bladder distention in the IC/BPS group are unknown and may have contributed to the results. There were no pathologic controls used, and no attempt was made to correlate GP1 reactivity with IC/BPS symptoms (Messing, 1994). Castration in female rabbits is associated with bladder mucosal changes resulting in increased mucosal permeability (Parekh et al., 2004). Birder et al. (2005) showed that FIC results in increased baseline production of nitric oxide as a result of iNOS. These changes in transmitter release may have a role in altering mucosal barrier properties.

VEGF plays a key role in bladder inflammation and is closely associated with the vascular alterations observed in patients with IC/BPS. VEGF and coreceptors (neuropilins [NRPs]) are strongly expressed in human bladder urothelium. NRP-2 and VEGFR-1 are significantly downregulated in IC/BPS when compared with control subjects (Saban et al., 2008). GAG modification of NRPs plays a critical role in modulating VEGF/NRP signaling (Shintani et al., 2006), suggesting another possible mechanism whereby a GAG deficiency could act by interfering with the functionality of this signaling system.

Some have cited the “potassium sensitivity test” as providing strong evidence for a population with mucosal leak (Parsons et al., 1994b). Parsons placed water or 0.4-M potassium chloride (KCl) intravesically into normal volunteers and IC/BPS patients. Water did not provoke pain in either group, but KCl provoked the symptom in 4.5% of normal subjects and 70% of IC/BPS patients. Symptomatic responses were reduced in patients on heparinoid therapy. Similar findings occured in patients with radiation cystitis (100%) (Parsons et al., 1994b), urinary infection (100%) (Parsons et al., 1998), detrusor instability (25%) (Parsons et al., 1998), and “urethral syndrome” (55%) (Parsons et al., 2001b) and in more than 80% of women with endometriosis, vulvodynia, and pelvic pain (Parsons et al., 2001a). Up to 33% of unselected Turkish women may test positive (Sahinkanat et al., 2008). Eighty-four percent of men with prostatitis also have a positive test result (Parsons and Albo, 2002). **The poor specificity of the potassium test** suggests that it does not provide unequivocal evidence of a permeability dysfunction. **Because it is known that the normal bladder epithelium can never be absolutely tight and that there is always some leak, however small** (Hohlbrugger and Sant, 1997)**, it is conceivable that the findings of pain with KCl are related to a hypersensitivity of the sensory nerves in this condition rather than to pathologic epithelial permeability, at least in some patients.** In fact, KCl administered intravesically to cats with FIC seems to *inhibit* afferent firing of peripheral Aδ fibers. Heightened sensitivity of afferent nerve fibers can explain KCl results without necessarily evoking increased permeability (Lutgendorf and Kreder, 2005; Roppolo et al., 2005). Intravesical administration of KCl has since been proposed as a diagnostic test for IC/BPS (Parsons et al., 1998) (see later).

How central abnormal epithelial permeability is to IC/BPS is, however, by no means clear. Tamm-Horsfall protein (THP), a high-molecular-weight glycoprotein synthesized exclusively by the ascending loop of Henle and the distal tubule of the kidney, has been studied as a potential marker of urothelial permeability. Fowler provided graphic data that the urothelium might be leaky in IC/BPS. With immunohistochemical techniques, his group assayed the bladder biopsy specimens of 14 IC/BPS patients and 10 normal controls for intraurothelial THP to assess indirectly the in vivo permeability of the urothelium. Eight pathologic controls were also assessed. Ten of 14 IC/BPS patients versus 1 of 18 controls demonstrated intraurothelial THP (Fowler et al., 1988). Serum THP autoantibody is higher in IC/BPS patients versus controls (Neal et al., 1991). It is known that excretion rates of THP vary widely, even in repeat samples taken from the same individual (Reinhart et al., 1990).

Subsequent studies in IC/BPS have failed to show differences in the presence of intraurothelial THP in the IC/BPS population versus controls, and in antibody reactivity to THP (Stein et al., 1993; Stone et al., 1992). Parsons reported that the THP protein is qualitatively different in patients with IC/BPS than in controls, even if the urinary concentration of the protein is the same (Argade et al., 2013; Parsons et al., 2007, 2011). Bade et al. (1996) failed to find THP in bladder tissue from 10 IC/BPS patients. Others have suggested that when THP is seen in bladder tissue, it is an incidental finding of no clinical significance. The finding of intraurothelial THP has not been shown to be a harbinger of IC/BPS or any other bladder disorder (Truong et al., 1994).

Finally, we must look at a body of literature that has failed to find GAG abnormality or hyperpermeability. Ultrastructural, biochemical, and functional studies of bladder GAG have not supported this theory (Collan et al., 1976; Dixon et al., 1986; Johansson and Fall, 1990; Ruggieri et al., 1991). Nickel et al. (1993) reported on use of sophisticated electron micrography with a specific antimucus, antisera stabilization technique to study the ultrastructural morphologic appearance of the GAG layer. No significant difference in the morphologic appearance of the mucus or GAG layer was noted in IC/BPS versus controls. Urinary chondroitin sulfates, heparan sulfate, and total sulfated GAGs normalized to creatinine are not altered in IC/BPS (Erickson et al., 1997b). Although an increased ratio of total GAGs to sulfated GAGs in IC/BPS may indicate an altered GAG layer, whether it reflects a cause or is a result of the primary pathologic process(s) is unknown (Wei et al., 2000). This leaves one to postulate an as-yet-unknown functional abnormality, rather than GAG deficiency, to account for any increase in permeability.

Chelsky et al. (1994) measured bladder permeability in IC/BPS using direct measurement by transvesical absorption of technetium-99m diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA). Although some IC/BPS patients had a more permeable bladder than others, the same was true for normal volunteers. Increased permeability in the IC/BPS group could not be demonstrated. However, 3 IC/BPS patients had marked absorption of DTPA and may represent a subpopulation of patients with increased epithelial permeability. Intravesical instillation of 10% and 20% ethanol in rabbits was reported to be a reliable quantitative measure of bladder hyperpermeability by the San Diego group (Monga et al., 2001) and subsequently failed to demonstrate bladder permeability in humans with IC/BPS (Gordon et al., 2003).

Overall, it does seem that there is a population of IC/BPS patients with

increased epithelial permeability, but the issue is far from closed. Increased mucosal permeability is nonspecific and a consequence of bladder inflammation, and also occurs with cyclophosphamide-induced bladder injury, bacterial infection, and cystitis following intravesical challenge with antigen after sensitization (Engelmann et al., 1982; Kim et al., 1992)**. It may also be a consequence of aging itself** (Jacob et al., 1978)**. Whether this represents a primary cause of IC/BPS or merely reflects the result of an as-yet-unidentified source of inflammation is unclear.** Treatments that tend to damage GAG, including transurethral resection and laser of ulcerated areas, bladder distention, silver nitrate administration, Clorpactin administration, and administration of the organic solvent dimethyl sulfoxide (DMSO) have all been used with varying results to treat IC/BPS.

One does not need increased permeability of the mucosa as a foundation for the many potential causes or contributing factors to IC/BPS. Enhanced adenosine triphosphate (ATP) release from the urothelium of patients with IC/BPS has been described (Kumar et al., 2007). This non-neuronal ATP may act as a sensory neurotransmitter. Increased purinergic activity thus may lead to a condition in which the bladder is oversensitive to distention. Increased permeability and epithelial dysfunction must be only a part of the story.

Key Points: Epithelial Permeability

- There is a population of IC/BPS patients with increased epithelial permeability.
- Increased mucosal permeability is nonspecific and a consequence of bladder inflammation. It also occurs with cyclophosphamide-induced bladder injury, bacterial infection, and cystitis following intravesical challenge with antigen after sensitization.
- It is unclear if this represents a primary cause of IC/BPS or merely reflects the result of an as-yet-unidentified source of inflammation.

Inhibition of Uroepithelial Cell Proliferation: Antiproliferative Factor

The finding that cells from the bladder lining of normal controls grow

significantly more rapidly in culture than cells from IC/BPS patients led Keay et al. (1996) **at the University of Maryland to the discovery of an APF produced by the urothelium of IC/BPS patients.** Normal bladder cells were cultured in the presence of urine from patients with IC/BPS, asymptomatic controls, bacterial cystitis, and vulvovaginitis. Only urine from IC/BPS patients inhibited bladder cell proliferation (Keay et al., 1998b). **The presence of APF was found to be a sensitive and specific biomarker for IC/BPS patients who met NIDDK criteria (Keay et al., 2001a).** It was found in bladder urine but not in renal pelvic urine of IC/BPS patients, indicating **production by the bladder urothelial cells** (Keay et al., 1999). Subsequent studies indicated **that APF is associated with decreased production of heparin-binding epidermal growth factor–like growth factor (HB-EGF)** (Keay et al., 2000)**. APF activity was related to increased production of epidermal growth factor (EGF), insulin-like growth factor-1, and insulin-like growth factor binding protein-3** by the bladder cells from IC/BPS patients but not by the cells from healthy bladders. Studies of IC/BPS patients and asymptomatic controls showed **urine levels of APF, HB-EGF, and EGF to reliably separate IC/BPS from controls** (Erickson et al., 2002; Keay et al., 2001b).

APF levels in the urine were found to discriminate between men with IC/BPS versus those with CPPS or nonbacterial prostatitis (Keay et al., 2004a). APF activity dropped significantly in IC/BPS patients within 2 hours after hydrodistention (Chai et al., 2000b) and after 5 days of sacral neuromodulation (SNM) (Chai et al., 2000a). Cell culture studies showed that APF actually caused a decrease in HB-EGF and an increase in EGF, mirroring the differences in urine levels of these growth factors between IC/BPS patients and controls and suggesting that APF is the primary abnormality (Keay et al., 2000).

Whereas APF may prove to be a useful marker for IC/BPS, it may also unlock the cause of the syndrome. **It has been hypothesized by Keay et al.** (2003) **that IC/BPS may result from an inhibition of bladder epithelial cell proliferation caused by APF, which is mediated by its regulation of growth factor production from bladder cells. Conceivably, any of a variety of injuries to the bladder (infection, trauma, and overdistention) in a susceptible individual may result in IC/BPS if APF is present and suppresses production of HB-EGF** (Keay and Warren, 1998). Theoretically, if production of APF could be “turned off” by genetic techniques or its effects were nullified by an APF antagonist (Keay et al., 2011) or exogenous HB-EGF, the clinical syndrome might be prevented (Yang et al., 2012a). HB-EGF functionally antagonizes APF activity via a mitogen-activated protein kinase pathway activation (Kim et al., 2009).

APF has been purified and proved to be a **frizzled 8 protein that belongs to a newly discovered family of proteins that seem to be important in the development of nerve tissues, skin, and the lining of organs** (Keay et al., 2004b). The frizzled family of receptors is critically involved in embryogenesis, and there is substantial evidence that members of this family also regulate tissue homeostasis in many different organs in the adult (Schulte and Bryja, 2007).

It appears that the cell cycle regulatory protein p53 is an important mediator of APF-induced effects on bladder epithelial cells (Kim et al., 2007). APF treatment suppresses cell proliferation by cell cycle arrest of human bladder urothelial cells. Evidence shows that p53 levels increase significantly after APF stimulation; p53 downregulation enhances the suppressive effect of APF on cell growth; and overexpression of p53 induces cell cycle arrest in the absence of APF. APF upregulates cellular p53 levels via functional attenuation of the USP2a-MDM2 pathway, resulting in p53 accumulation and growth arrest (Kim et al., 2012). It is possible that targeting of p53 could be a means of abrogating the pathologic effects of urinary APF and lead to new options for clinical therapy.

Studies are ongoing to confirm the research by Keay et al. and expand on its significance in diagnosis and development of a rational treatment approach (Rashid et al., 2004). The development of animal models with specific signaling abnormalities found in IC/BPS epithelial, endothelial, smooth muscle, neuronal, or immune cells to determine whether these animals develop a disease similar to the human disorder would be an extremely useful and potentially very productive pathway to learn more about potential therapeutic pathways (Keay, 2008).

Key Points: Antiproliferative Factor

- The frizzled 8 protein termed *antiproliferative factor (APF)* has been proposed as a marker to identify patients with IC/BPS.
- It is secreted by bladder epithelial cells of IC/BPS patients and inhibits bladder epithelial cell proliferation through mediation of growth factor production. Thus, it could be a proximal cause of the syndrome in many

patients.

Neurobiology

Nonadrenergic noncholinergic mechanisms play significant roles in mediating direct functional effects and indirect effects by affecting inflammation (Vesela et al., 2012).

Neuropeptides present in primary afferents and the dorsal horn of the spinal cord have an important role in the mediation of nociceptive input under normal conditions. Under pathologic conditions, such as during chronic inflammation or after peripheral nerve injury, the production of peptides and peptide receptors is dramatically altered, leading to a number of functional consequences (Wiesenfeld-Hallin and Xu, 2001). Inflammatory painful stimuli, especially if repeated, can chronically alter innervation, central pain-processing mechanisms, and tissue responses (Steers et al., 1997). It has been known for some time that the sensory nervous system can generate some of the manifestations of inflammation (Dimitriadou et al., 1991, 1992; Foreman, 1987). Activation of capsaicin-sensitive afferent neurons locally and centrally may be involved in stress-related pathologic changes in the rat bladder (Ercan et al., 2001). **Activation of sensory nerves, specifically pain fibers, is known to trigger neurogenic inflammation through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide (CGRP), and subsequent increase in vascular permeability, with leukocyte adhesion and tissue edema. The neuropeptide mediators have been shown to also cause degranulation of mast cells with release of additional potent mediators of inflammation and to lead to injury and increased permeability of epithelial surfaces** (Elbadawi and Light, 1996). An increase in nerve fibers within the suburothelium and detrusor muscle in ulcerative IC/BPS has been noted (Lundeberg et al., 1993). A correlation was found between the number of nerve fibers and numbers of mast cells and between the number of nerve fibers and the amount of histamine. **Consolidating the leaky urothelium theory and mast cell activation, neurogenic inflammation is an attractive proposal for the cause and can readily accommodate infectious, immunologic, and autoimmunologic mechanisms as factors** (Elbadawi and Light, 1996).

Harrison proposed that small-diameter sensory nerves in the bladder wall may have a role in the transmission of the sensation of pain and in the triggering of inflammatory reactions rather than forming the afferent limb of the micturition reflex (Harrison et al., 1990). Abelli demonstrated in the rat urethra that mechanical irritation alone can cause neuropeptide release from peripheral capsaicin-sensitive primary afferent neurons, resulting in neurogenic inflammation (Abelli et al., 1991). Extracellular ATP can act through the purinergic receptor subtype $P2X_3$ to transmit a pain signal to the central nervous system. These subunits expressed by cultured IC/BPS bladder urothelial cells are upregulated during in vitro stretch and may phenotypically mimic sensory neurons (Sun and Chai, 2004). Purinergic receptor antagonists that are orally bioavailable may provide an avenue for a potential therapeutic strategy (Burnstock, 2012).

Several pieces of additional information support a theory of neurogenic inflammation. Levels of nerve growth factor are elevated in bladder biopsy specimens from IC/BPS patients (Lowe et al., 1997), providing another potential therapeutic target (Ochodnicky et al., 2011). Studies in rats using pseudorabies virus clearly show that bladder inflammation can be induced from a somatic structure through a neural mechanism and that central nervous system dysfunction can bring about a peripheral inflammation (Doggweiler et al., 1998). Pelvic nerve stimulation in the rat increases urothelial permeability, which is antagonized by capsaicin, indicating both an efferent effect of afferent nerves and afferent-mediated neuroepithelial interaction (Lavelle et al., 1999). Ca^{2+}/calmodulin-dependent protein kinase II has been implicated in the neurogenic cystitis pelvic pain induced in a mouse model with pseudorabies virus infection (Yang et al., 2012b).

Numerous studies indicate increased sympathetic activity in IC/BPS. Hohenfellner et al. (1992) suggested that IC/BPS is associated with increased sympathetic outflow into the bladder and altered metabolism of vasoactive intestinal polypeptide and NPY. NPY inhibits bladder afferents and therefore may be involved in autonomic disturbances affecting the bladder. Elevation of urinary catecholamines in IC/BPS patients and plasma catecholamines in cats with FIC has been observed (Buffington and Pacak, 2001; Stein et al., 1999), as has an increased density and number of nerve fibers immunoreactive for tyrosine hydroxylase in IC/BPS patients (Peeker et al., 2000a). Whether these changes reflect a cause of IC/BPS or are merely the result of long-standing intense pain and a severely pathologic voiding pattern is unknown.

Galloway proposed that the changes in IC/BPS may be explained by an increase in sympathetic discharge, analogous to that seen in reflex sympathetic dystrophy (RSD) (now termed complex regional pain syndrome) of limbs

(Galloway et al., 1991). The pathology in RSD is the development of abnormal synaptic activity between sensory afferent and sympathetic efferent neurons. Nerve cells in the spinal cord become hypersensitive to sensory input, and this sustains abnormal sympathetic outflow and corresponding vasomotor dysregulation. The excess sympathetic outflow leads to constriction of blood vessels and tissue ischemia, setting up further sensory changes and perpetuating the cycle. In RSD, there is usually a trigger event leading to these changes. With the acute phase of RSD, regional signs of inflammation are evident in the affected extremity. One school of thought believes an inflammatory response to an injury initiates RSD. Increased capillary permeability is a direct result (Goris and Jan, 1998). Perhaps a urinary infection could trigger such a pathologic cycle in some IC/BPS patients.

Herbst produced bladder lesions in a dog resembling the ulceration of IC/BPS by ligating the blood vessels to the posterior bladder wall and infecting the area with *Streptococcus viridans* (Herbst et al., 1937). Studies using laser Doppler flowmetry have shown that when the bladder is distended under anesthesia, blood flow increases in control patients to a statistically significant degree as compared with IC/BPS patients (Irwin and Galloway, 1993; Pontari et al., 1999). Another study has purported to show that topical heparin therapy can normalize urothelial permeability and vesical blood flow in IC/BPS (Hohlbrugger et al., 1998). Decreased microvascular density has been described in the suburothelium but not in the deeper mucosa in bladder biopsy specimens from women with IC/BPS (Rosamilia et al., 1999a). Hyperbaric oxygen has been suggested to have a limited effectiveness for the treatment of IC/BPS (Gallego-Vilar et al., 2013; Loran et al., 2011; Tanaka et al., 2007, 2011; van Ophoven et al., 2004b, 2006) and radiation-induced cystitis (Weiss and Neville, 1989). The mechanism of action has been postulated to be related to the overexpression of hypoxia-inducible factor-1 and VEGF in IC/BPS bladders (Lee and Lee, 2011).

If lumbar sympathetic blocks can decrease the pain of IC/BPS, a role of the sympathetic nervous system in IC/BPS pathogenesis is a reasonable supposition (Doi et al., 2001; Irwin et al., 1993). Buffington demonstrated an increase in sympathetic activity in cats with FIC (Buffington and Pacak, 2001; Buffington et al., 2002). Similar findings were reported in a small study of IC/BPS patients (Dimitrakov et al., 2001), and sympathetic activity may be an underlying common denominator in many disorders associated with IC/BPS (Buffington, 2004).

Nevertheless, **no studies performed to date indicate that any case of**

IC/BPS is related to the syndrome of RSD (complex regional pain syndrome) (Ratliff et al., 1994). No single test can be used to exclude sympathetically maintained pain, and there are no clear symptoms that predict sympathetically mediated pain (Baron, 2000). In the animal model, bladder ischemia is associated with DO or impaired detrusor contraction, not sensory urgency (Azadzoi et al., 1999). Patients with RSD who have voiding symptoms rarely have a picture that would be confused with IC/BPS (Chancellor et al., 1996).

Before leaving the neurogenic causative theory, it is important to note that the nervous system itself almost surely contributes to the chronic nature of this pain syndrome, regardless of initiating cause (Vrinten et al., 2001). Repetitious stimulation of a peripheral nerve at sufficient intensity to activate C fibers results in a progressive buildup of the magnitude of the electrical response recorded in the second-order dorsal horn neurons. This “windup” phenomenon is central to the concept of chronic pain. Biochemically it is dependent on activation of *N*-methyl-D-aspartate (NMDA) receptors in the spinal cord (Bennett, 1999). With persistent NMDA receptor activation, spinal cord cells undergo trophic changes, and the pain resulting from subsequent stimulation becomes exaggerated and prolonged. This “pain memory” in the spinal cord may be what causes IC/BPS patients to become refractory to different therapies (Brookoff and Sant, 1997). NMDA-receptor–driven formation of new connections in the spinal cord may account for the expansion of the pain field.

Upregulation of the central nervous system and augmented sensory processing have been referred to as non-nociceptive pain (NNP) (Bennett, 1999). Chronic neuropathic pain may continue after the resolution of tissue damage and persist on the basis of a maladaptive mechanism (Urban et al., 2002).

Sun et al. followed up on Burnstock's observation that ATP has a role in mechanosensory transduction by the epithelial lining of hollow viscus organs such as bladder (Burnstock, 1999; Sun et al., 2001). Stretched epithelial cells lining hollow organs release ATP, which acts on purinergic nociceptive receptors on subepithelial sensory nerve terminals. Sun et al. (2001) found that ATP was significantly elevated in the urine of IC/BPS patients, and the stretch-activated release of ATP was augmented in IC/BPS urothelium.

Neurogenic inflammation may be the cause of some cases of IC/BPS or may be the result of other initiating causative events. It is not incompatible with the central role of the mast cell, or with the leaky epithelium theory. It conceivably could result in the appearance of autoimmune phenomena or result from an episode of infection. The central nervous system may also be implicated in dysregulation of the pelvic floor resulting in chronic pelvic pain and contributing to IC/BPS (Zermann et al., 1999), and perhaps in the rare cases of IC/BPS that chronologically seem to relate to trauma or pelvic surgery (Zermann et al., 1998). It is an etiologic theory that provides fertile ground for new treatment possibilities.

Key Points: Neurogenic Inflammation

- Numerous studies indicate increased sympathetic activity in IC/BPS. Activation of sensory pain fibers is known to trigger neurogenic inflammation through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide.
- Neurogenic inflammation may be the cause of some cases of IC/BPS. Chronic neuropathic pain may continue after the resolution of tissue damage and persist on the basis of a maladaptive mechanism.

Pelvic Organ Cross-Sensitization

Clinical observations of viscerovisceral referred pain in patients with gastrointestinal and genitourinary disorders suggest an overlap of neurohumoral mechanisms underlying both bowel and urinary bladder dysfunction. Close proximity of visceral organs within the abdominal cavity complicates identification of the exact source of chronic pelvic pain, where it originates, and how it relocates with time. Cross-sensitization among pelvic structures may contribute to chronic pelvic pain of unknown cause and involves convergent neural pathways of noxious stimulus transmission from two or more organs**. Inflammation, nerve injury, ischemia, peripheral hyperalgesia, metabolic disorders, and other pathologic conditions can dramatically alter the function of directly affected pelvic structures and organs located next to a damaged domain** (Malykhina, 2007). It has been demonstrated in a rat model that acute colitis can sensitize lumbosacral spinal neurons receiving input from the urinary bladder (Qin et al., 2008). Acute colitis and acute cystitis in the rat model can each cross-sensitize the bladder and colon, respectively (Pezzone et al., 2005).

It is thought that chronic widespread pain in chronic fatigue syndrome and

FMS (disorders associated with IC/BPS in many patients) can be a consequence of central sensitization. Central sensitization is an increased central neuronal responsiveness and causes hyperalgesia, allodynia, and referred pain and hyperalgesia across multiple spinal segments, leading to chronic widespread pain. Triggers include windup or temporal summation, dysregulated descending inhibitory pathways, and upregulated facilitatory modulation. Windup or temporal summation is the result of repetitive noxious stimuli, leading to an increase in electrical discharges in the dorsal horn. Inhibitory modulation can be impaired by abnormalities in the central nervous system, and the facilitatory pain pathways can be stimulated by certain behavioral and cognitive factors (Meeus and Nijs, 2007).

It is possible that a combination of central sensitization and pelvic cross-talk may account for the association of IC/BPS with bowel symptoms in some patients, and the use of dietary alterations for managing the severity of IC/BPS symptoms. Relatively minor gut stimuli that otherwise cause no symptoms could exacerbate established, bladder-driven pelvic pain, because even slight increases of inputs from a second site such as the gut might lead to a sum of inputs that is considerably elevated above a threshold necessary to induce pain (Klumpp and Rudick, 2008; Rudick et al., 2007). Central pain amplification might also account for the increased startle responses described in female IC/BPS patients in the context of a threat of abdominal pain (Twiss et al., 2009).

Key Points: Sensitization of Neural Pathways

- Cross-sensitization among pelvic structures may contribute to CPPS.
- Neural pathways from two or more organs, one or both of which are carrying noxious stimuli transmissions, may converge. Theoretically, this could lead to alteration of the function of not only the directly affected pelvic structures, but organs located nearby as well.

Nitric Oxide Metabolism

Regulation of urinary NOS activity has been proposed to be of importance for immunologic responses in IC/BPS. The oral administration of L-arginine, the substrate for nitric oxide production (Moncada and Higgs, 1993), has been shown to increase nitric oxide–related enzymes and metabolites in the urine of patients with IC/BPS (Smith et al., 1996). It has been reported that differences in nitric oxide evaporation between ulcerative and non-HL IC/BPS allows for subtyping of cases meeting the NIDDK criteria. This could potentially replace cystoscopy as a tool for identifying ulcerative IC/BPS (Logadottir et al., 2004). Increased levels of endogenously formed nitric oxide correspond to increased iNOS in mRNA expression and protein levels in IC/BPS patients. iNOS has been found to be localized to the urothelium and also has been found in macrophages in the bladder mucosa. Whether high levels of endogenously formed nitric oxide are a part of the pathogenesis in IC/BPS and whether it has a protective or damaging role remains to be elucidated (Koskela et al., 2008).

Urine Abnormalities

In general, current theories of pathogenesis involve access of a component of urine to the interstices of the bladder wall, resulting in an inflammatory response induced by toxic, allergic, or immunologic means. The substance in the urine may be a naturally occurring one—a substance that acts as an initiator only in particularly susceptible individuals—or may act like a true toxin, gaining access to the urine by a variety of mechanisms or metabolic pathways (Wein and Broderick, 1994). Clemmensen noted that 8 of 11 IC/BPS patients had positive skin reactions to patch tests with their own urine (Clemmensen et al., 1988). Immediate reactions were not observed, and the histology suggested a toxic rather than an allergic reaction. Lynes was unable to find a urinary myotropic substance unique to IC/BPS patients (Lynes et al., 1990b). The San Diego group found IC/BPS urine to result in higher cell death of cultured transitional cells than normal urine, suggesting a toxic compound in the urine of some IC/BPS patients (Parsons and Stein, 1990). They identified heat-labile, cationic components of low molecular weight that bind to heparin and that, when separated from the bulk of urinary wastes, are cytotoxic to urothelial cells and underlying smooth muscle cells (Parsons et al., 2000). They reported a 12% increase in 72-kDa stress protein in cells treated with urine from IC/BPS patients compared with controls (Ito et al., 1998).

Others have not been able to demonstrate in vitro cytotoxicity (Beier-Holgersen et al., 1994) or immunohistochemical changes in the nociceptive centers in the spinal cord or bladder wall when IC/BPS urine was compared with control urine (Baykara et al., 2003). Efforts to induce an IC/BPS-like picture in the rabbit bladder from exposure to urine of IC/BPS patients have failed to demonstrate conclusive changes (Kohn et al., 1998; Perzin et al., 1991; Ruggieri et al., 1993). Increased levels of soluble mediators associated with activation of sensory neurons and/or mast cells have been found in the urine of both IC/BPS and bladder cancer patients (Okragly et al., 1999).

Circumstantial evidence for the toxicity of IC/BPS urine is suggested by the failure of substitution cystoplasty and continent diversions in some of these patients because of the development of pain or contraction of the bowel segment over time (Baskin and Tanagho, 1992; Lotenfoe et al., 1995; Nielsen et al., 1990; Trinka et al., 1993), and by the histologic findings similar to IC/BPS found to occur in bowel used to augment the small-capacity IC/BPS bladder (McGuire et al., 1973; Singh and Thomas, 1996). Intestinal mucosa in contact with urine undergoes progressive changes for as long as 3 years after surgery, and the significance of the histologic IC/BPS-like changes has been questioned (Davidsson et al., 1996; MacDermott et al., 1990).

Role of Genetics in Bladder Pain Syndrome

Warren et al. (2001) reported findings from a small cohort of twins in which a greater concordance of IC/BPS was demonstrated among monozygotic than among dizygotic twins. This finding suggested that there could be a genetic susceptibility to IC/BPS. A later study by the same research group suggested that adult female first-degree relatives of patients with IC/BPS may have a prevalence of IC/BPS 17 times that found in the general population (Warren et al., 2004). This, coupled with the previously reported twin data, suggests but does not prove that a genetic component adds to the susceptibility to IC/BPS. Looking at an identical twin model with 246 twin sisters, Tunitsky et al. (2012) found that 9% were identified as having a moderate or high risk for IC/BPS, with 5 twin sets in which both twins met the criteria. They concluded that IC/BPS symptom scores within twin pairs were moderately correlated, implying some genetic component.

A Swedish study that included more than 25,000 twins born from 1959 to 1985 compared monozygotic and dizygotic twins with symptoms of IC/BPS. Overall IC/BPS prevalence was 1.1% of men and 2.4% of women. In women, genetic factors contributed less than one-third of the total variation in susceptibility to IC/BPS. Lower male prevalence prevented determinations of genetic contribution. The authors concluded that the influence of environmental factors in the development of IC/BPS in women is substantial, whereas genetic influences are of only modest importance (Altman et al., 2011).

The report by Weissman et al. (2004) of the increased frequency of IC/BPS in patients and their first-degree relatives with panic disorder and other seemingly disparate disorders suggests that there is a familial syndrome consisting of IC/BPS and other disorders of possible autonomic or neuromuscular dysfunction. A more recent case-control study by the same group suggested that this syndrome might include other anxiety disorders as well, and that families with and without this collection of symptoms were genetically distinguishable on chromosome 13 (Talati et al., 2008).

Gene-expression profiles in cultured IC/BPS cells have been investigated and compared with controls (Erickson et al., 2008a). Few differences were appreciated, indicating that, rather than being genetically based, the abnormal urothelium in IC/BPS may be caused by post-translational changes and/or to the bladder environment. It has been suggested that epigenetic reprogramming mechanisms in the bladder may provide an explanation for uroepithelial cell, mast cell, and nerve cell abnormalities in IC/BPS, and propagation of this altered state in the absence of the signal that may have triggered it (Elgavish, 2009). Viewing medically unexplained symptoms from the perspective of underlying developmental influences involving epigenetic modulation of gene expression that affect function of a variety of organs based on familial predispositions rather than from the traditional viewpoint of isolated organ-originating diseases may open up new areas of investigation for this class of “functional” disorders (Buffington, 2009).

Other Potential Causes

Various other etiologic theories have been proposed (Ratliff et al., 1994), but none has received much scientific support. Voiding almost hourly, always having to be aware of how far the nearest restroom facilities are, and suffering constant pain would be expected to lead to psychological stress. However, could there be individual differences in the propensity to develop IC/BPS that result from a dysregulation of anxiety and mood (Bodden-Heidrich, 2004; Nesse, 1999)? Childhood sexual trauma has been implicated as a causative factor for the disease (Mayson and Teichman, 2009; Nickel et al., 2011; Tietjen et al., 2010). **There are no data currently to suggest that stress itself *initiates* the chronic syndrome of IC/BPS, although it certainly can increase symptom severity** (Lutgendorf et al., 2000). Cats restricted to indoor living are five times more likely to have urinary problems than cats allowed outdoors (Buffington et al., 2002). Female patients with IC/BPS have been shown to have increased heart rate at baseline and throughout a laboratory mental stress challenge, but did not demonstrate greater autonomic reactivity to stress (Lutgendorf et al., 2004). Until stress can be shown to produce IC/BPS de novo in humans, it is just as reasonable to speculate that the stress is a result of the syndrome as a primary cause of it.

Speculation that abnormality in or obstruction of lymphatics or vascular structures is causative has never been borne out. The fact that some of these patients have had a hysterectomy probably relates more to the attempt of the physician to treat chronic pelvic pain than to postsurgical change as a cause of IC/BPS (Chung, 2004).

The knowledge that there is at least a 5 : 1 female-to-male preponderance immediately makes the role of the hormonal milieu potentially important (Bjorling and Wang, 2001). Paradoxically, it is known that estrogens can control hematuria in hemorrhagic cystitis, perhaps by decreasing the fragility of the mucosal microvasculature of the bladder (Liu et al., 1990). Estradiol augments whereas the estrogen receptor blocker tamoxifen inhibits mast cell secretion (Vliagoftis et al., 1992). Bladder mast cells express high-affinity estrogen receptors, and there is a higher number of such cells present in patients with IC/BPS compared with controls. Although this may help explain why IC/BPS is so common in women, the hormonal role can only account for the propensity of IC/BPS to occur in females, not the ultimate cause.

HTPFD has been associated with IC/BPS for many years (Schmidt and Vapnek, 1991), and trials suggest that treatment of the pelvic floor can be effective in ameliorating symptoms (Doggweiler-Wiygul et al., 2001, 2002; FitzGerald et al., 2012; Holzberg et al., 2001; Lilius et al., 1973; Oyama et al., 2004; Weiss, 2001). Speculation that abnormalities of the pelvic floor muscular function may contribute to the cause of some cases of CPPS in men is well accepted (Segura et al., 1979; Schmidt and Vapnek, 1991; Zermann et al., 1999), and a similar case might be made for patients with IC/BPS, though scientific support for a direct causative relationship is lacking.

One can understand the complexity of IC/BPS by looking at the myriad theories of etiology and the associated disorders that have been described. Complex functional disorders with patterns of comorbidity, in which there is overlap of what had once been regarded as independent syndromes, appear to fall outside the biomedical framework. It has been said that they “fully escape the profession's divided and divisive grip. By their mere existence, they challenge the medical community's view of the body, their understanding of what it is to be human and question whether present approaches to obtaining knowledge are adequate for helping people who suffer” (Kirkengen and Ulvestad, 2007).

Key Point: Etiology

- Both stress and HTPFD can contribute to IC/BPS symptom severity and may be targets for treatment. Whether they can be contributing initiators of the syndrome complex is unclear at this time. The 5 : 1 female preponderance suggests hormonal involvement in the cause, but if recent data suggest that male prevalence is close to female prevalence, this conventional wisdom will need revision (Suskind et al., 2013).

Pathology

There is no histology pathognomonic of IC/BPS. This is not surprising given a medical condition that is primarily based on the complaint of visceral pain; and this reinforces the need for accurate phenotyping. Other factors that may obfuscate histologic studies include: duration of disease, recent trauma (e.g., hydrodistention), history of bacterial cystitis, and even the location or type of biopsy. These factors align with the great variation in the reported histologic appearance of biopsy specimens from IC/BPS patients, and even the microscopic variation among biopsies taken from the same patients over time (Gillenwater and Wein, 1988).

Histologic features of IC/BPS can be remarkably bland. On the other hand, inflammatory features can be seen in 24% to 76% of patients without a visible HL (Erickson et al., 2008b). Rosamilia presented data comparing light microscopic changes of IC/BPS bladder biopsies to controls (Hanno et al., 2005a; Rosamilia et al., 2003). Although epithelial denudation, submucosal edema, congestion and ectasia, and inflammatory infiltrate were increased in the IC/BPS group, histologic parameters were normal and indistinguishable from control subjects in 55% of IC/BPS specimens. Method of biopsy can be important in interpreting findings, because transurethral resection biopsy specimens tend to show mucosal ruptures, submucosal hemorrhage, and mild inflammation (Johansson and Fall, 1990), whereas histology is normal approximately half the time with cold-cup forceps biopsy specimens (Lynes et al., 1990a; Mattila, 1982; Rosamilia et al., 2003.

Striking differences in histopathology, primarily based on severity of inflammatory events, distinguish IC/BPS with HLs (IC/BPS+HL) and IC/BPS without HLs (IC/BPS-HL). This point, along with little data to support transition from IC/BPS-HL to IC/BPS+HL (Fall et al., 1987)**, argues that these conditions may be completely separate disorders.** Johansson and Fall (1990) evaluated 64 patients with IC/BPS+HL and 44 with IC/BPS–HL. The former group had mucosal ulceration and hemorrhage, granulation tissue, intense inflammatory infiltrate (predominantly plasma cells and lymphocytes), elevated mast cell counts, and perineural infiltrates. The IC/BPS–HL group, despite having the same severe symptoms, had a relatively unaltered mucosa with a sparse inflammatory response, the main feature being multiple, small mucosal ruptures and suburothelial hemorrhages that were noted in a high proportion of patients. As these specimens were almost all taken immediately after hydrodistention, how much of the admittedly minimal findings in the IC/BPS–HL group was purely iatrogenic is a matter of speculation. The same group later reported the frequent finding of completely normal biopsy specimens in IC/BPS–HL patients (Johansson and Fall, 1994). Furthering these results, Maeda et al. (2015) found a severe lymphoplasmocytic infiltrate in 93% of IC/BPS+HL biopsies versus only 8% of IC/BPS–HL biopsies. They identified epithelial denudation to be a distinct feature of IC/BPS+HL that is not confined to the HL, and suggests a fieldlike change to the bladder surface. Although most studies report few inflammatory events associated with IC/BPS–HL (Akiyama et al., 2019), a recent study described more severe bladder wall fibrosis and increased mast cell infiltration in these patients (Kim et al., 2017). Several studies have suggested that a severely abnormal pathology may be associated with a poor prognosis (McDougald and Landon, 2003; Nordling et al., 2004); this is not necessarily the case (MacDermott et al., 1991a).

Mast cell proliferation, activation, and degranulation may play a role in the pathogenesis of IC/BPS (Theoharides and Stewart, 2017). Mast cells trigger inflammation that is associated with local pain, but the mechanisms mediating pain are unclear. In a murine model of neurogenic cystitis, Rudick et al. (2008) demonstrated that mast cells promote cystitis pain and bladder pathophysiology through the separable actions of histamine and TNF, respectively. Mast cell density has been repeatedly studied as a potential marker for IC/BPS, but results have been disparate (Gamper et al., 2015; Holm-Bentzen et al., 1987a; Larsen et al., 2008; Moore et al., 1992; Regauer et al., 2017) partially because of methodologic differences. A recent study employing immunohistochemical localization of mast cells with anti–mast cell tryptase found increased subepithelial and detrusor mast cell density in patients with IC/BPS+HL, but this finding was of low predictive value. Furthermore, there were no differences in mast cell density between IC/BPS–HL and specimens from patients with OAB (Gamper et al., 2015). Another study using digital quantitative analysis detailed the similarities of mast cell density between IC/BPS+HL and specimens with “chronic cystitis” and between IC/BPS–HL and normal controls. As one might expect, mast cell density correlated to general lymphoplasmocytic cell density (Akiyama et al., 2017). **Collectively, these findings suggest that mast cell counts, although perhaps relevant to pathogenesis, have no role in the diagnosis of IC/BPS.**

Specialized preparation of specimens may yield insights into pathophysiology and aid in diagnosis. Immunohistochemical staining techniques were used to identify nerve fibers, B-lymphocytes, the NGF receptor ($p75^{NTR}$), and mast cells performed on biopsy specimens from IC/BPS–HL, IC/BPS+HL, OAB, and normal control individuals. Sensory hyperinnervation, basal urothelial $p75^{NTR}$ staining, and an assessment of B-lymphocyte and tissue integrity enabled the differentiation of both IC/BPS+HL and IC/BPS–HL from OAB and normal control specimens (Regauer et al., 2017).

At this time, the role of histopathology in the diagnosis of IC/BPS is limited to those patients with HLs in whom one must rule out carcinoma and carcinoma in situ, eosinophilic cystitis, tuberculous cystitis, and any other entities with a specific tissue diagnosis (Hellstrom et al., 1979; Johansson and Fall, 1990; Tsiriopoulos et al., 2006).

Key Points: Pathology

- The role of histopathology is primarily to exclude other possible diagnoses that might be responsible for the symptoms.
- There is no histology pathognomonic of IC/BPS, and one cannot make the diagnosis on pathology alone in the absence of the cardinal symptoms.
- Completely normal-appearing bladder biopsy specimens in symptomatic patients are common.

Diagnosis

Current diagnostic strategies for IC/BPS are primarily based on its definition rather than strict research criteria established about 30 years ago. The definition —chronic pain, pressure, or discomfort associated with the bladder, usually accompanied by urinary frequency in the absence of any other identifiable cause (Hanno et al., 2005a, 2005b)—has been carefully crafted to incorporate noxious terms beyond “pain” that are commonly voiced by patients. The definition incorporates “urinary frequency” (that is often driven by the pain) but intentionally omits “urgency,” a term that is poorly understood by patients and clinicians alike and generally aligns with a diagnosis of OAB syndrome.

Perhaps the most challenging aspect to accurately diagnose IC/BPS is excluding other identifiable causes of symptoms. In the authors’ experience,

failure to diagnose other causes of pelvic pain that may occur with or without IC/BPS is one of the most common reasons for therapeutic failure.

Table 57.5 summarizes confusable diseases related to IC/BPS and their mode of exclusion based on diagnostic proposals and procedures modified from the ESSIC group (van de Merwe et al., 2008). **It is of utmost importance for the clinician to identify and treat all pelvic pain generators (usually in a stepwise fashion) for optimal success, and this is stressed in a suggested diagnostic algorithm modified from AUA guidelines (Fig. 57.5).**

TABLE 57.5

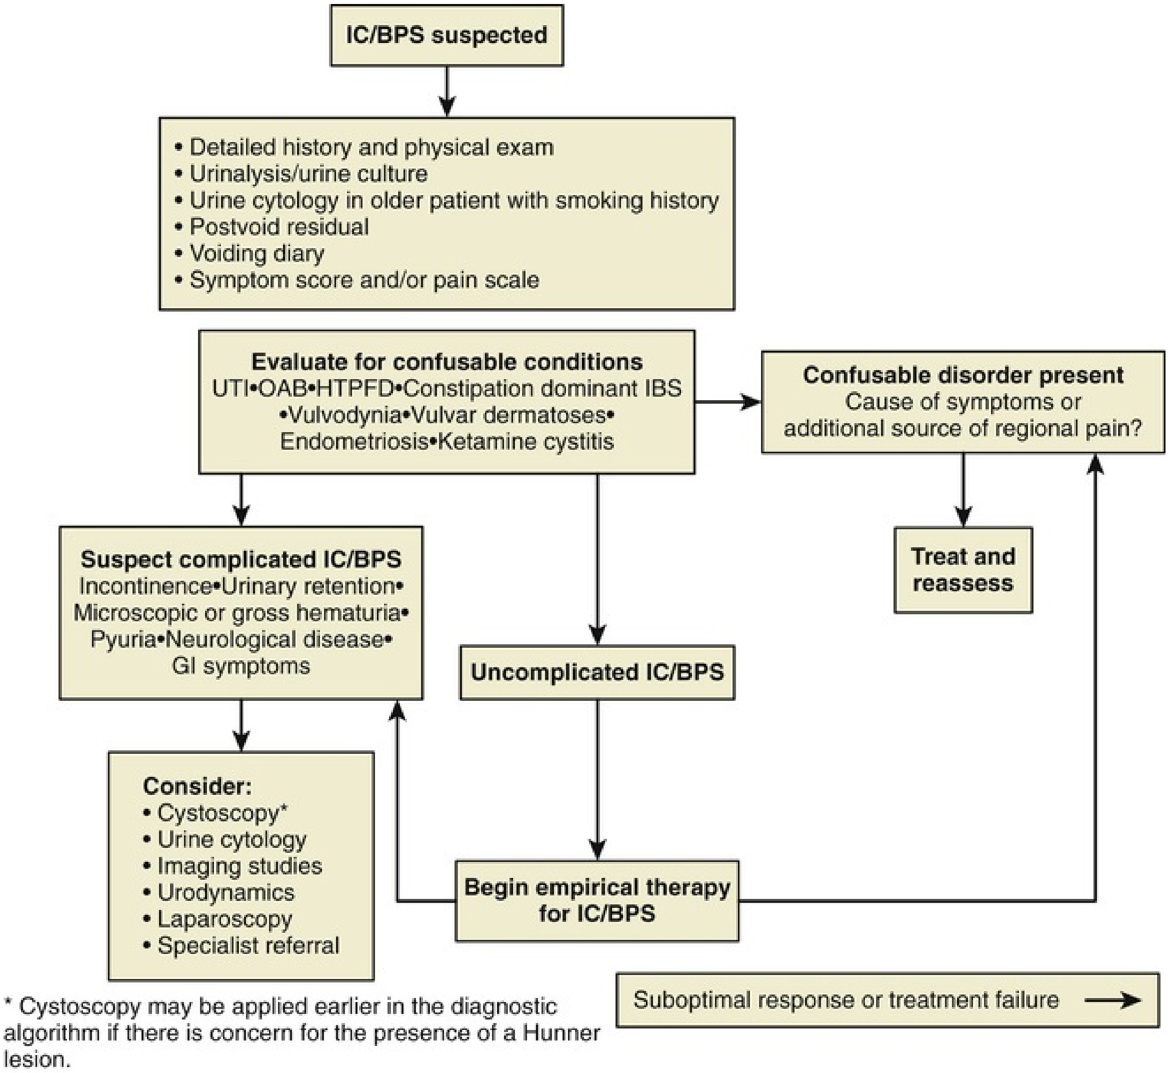
Disorders That May Be Mistaken for IC/BPS

CONFUSABLE DISORDER	EXCLUDED OR DIAGNOSED BY
Carcinoma and carcinoma in situ	Cystoscopy, biopsy
Infection with:	
Common intestinal bacteria	Routine bacterial culture
Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Mycoplasma genitalium, Corynebacterium urealyticum, Candida species, Mycobacterium tuberculosis	Special cultures Dipstick; if “sterile” pyuria, culture for *M. tuberculosis*
Herpes simplex, herpes zoster	Medical history, physical examination
Radiation	Medical history
Chemotherapy, including immunotherapy with cyclophosphamide	Medical history
Anti-inflammatory therapy with tiaprofenic acid	Medical history
Ketamine cystitis	Medical history
Bladder neck obstruction and neurogenic outlet obstruction	Medical history, urodynamic evaluation
Bladder stone; lower ureteral stone	Imaging or cystoscopy, CT
Urethral diverticulum	Medical history, physical examination, MRI
Colon cancer, diverticulitis, irritable bowel syndrome; inflammatory bowel disease	Medical history, physical examination, colonoscopy
Urogenital prolapse	Medical history, physical examination
Endometriosis, adenomyosis	Medical history, physical examination, imaging studies (i.e., MRI/pelvic

	ultrasonography) as appropriate
Pelvic congestion syndrome	Medical history, pelvic ultrasonography
Vaginal candidiasis	Medical history, physical examination, vaginal cultures as appropriate
Cervical, uterine, and ovarian cancer	Physical examination, pelvic ultrasonography
Vulvodynia	Medical history and physical examination
Incomplete bladder emptying (retention)	Postvoid residual urine volume measured by ultrasound evaluation
Overactive bladder	Medical history; urodynamic evaluation as appropriate
Prostate cancer	Physical examination, serum PSA
Benign prostatic obstruction	Medical history, physical examination, uroflowmetry and pressure-flow studies in selected cases
Chronic bacterial prostatitis	Medical history, physical examination, culture
Chronic nonbacterial prostatitis	Medical history, physical examination, culture
Pudendal nerve entrapment	Medical history, physical examination, nerve block may prove diagnosis
Abdominal wall hernia	Medical history, physical examination
Pelvic floor muscle–related pain	Medical history, physical examination

CT, Computed tomography; *MRI,* magnetic resonance imaging; *PSA,* prostate-specific antigen.

Modified from van de Merwe JP, Nordling J, Bouchelouche P, et al. Diagnostic criteria, classification, and nomenclature for painful bladder syndrome/interstitial cystitis: an ESSIC proposal. *Eur Urol* 53(1):60–67, 2008.



IC/BPS suspected
• Detailed history and physical exam
• Urinalysis/urine culture
• Urine cytology in older patient with smoking history
• Postvoid residual
• Voiding diary
• Symptom score and/or pain scale
Evaluate for confusable conditions
UTI•OAB•HTPFD•Constipation dominant IBS
•Vulvodynia•Vulvar dermatoses•
Endometriosis•Ketamine cystitis
Confusable disorder present
Cause of symptoms or
additional source of regional pain?
Treat and reassess
Suspect complicated IC/BPS
Incontinence•Urinary retention•
Microscopic or gross hematuria•
Pyuria•Neurological disease•
GI symptoms
Uncomplicated IC/BPS
Consider:
• Cystoscopy*
• Urine cytology
• Imaging studies
• Urodynamics
• Laparoscopy
• Specialist referral
Begin empirical therapy for IC/BPS
Suboptimal response or treatment failure
* Cystoscopy may be applied earlier in the diagnostic algorithm if there is concern for the presence of a Hunner lesion.

FIG. 57.5 Proposed diagnostic algorithm for evaluation of interstitial cystitis/bladder pain syndrome (IC/BPS). *GI,* Gastrointestinal; *HTPFD,* high-tone pelvic floor dysfunction; *IBS,* irritable bowel syndrome; *OAB,* overactive bladder; *UTI,* urinary tract infection. Modified from Hanno PM, Burks DA, Clemens JQ, et al. AUA guideline for the diagnosis and treatment of interstitial cystitis/bladder pain syndrome. *J Urol* 185(6):2162–2170, 2011.

A detailed history, physical examination, and urine studies will, in almost all circumstances, give the clinician enough clues to exclude common well-described sources of pelvic pain that might be confused with IC/BPS (Box 57.2). As described in guidelines suggested by the American Urological Association, basic urine studies including a urinalysis and urine culture are needed. The urine culture is suggested to exclude low counts of bacteria that might produce symptoms in the face of a negative urinalysis (Duldulao et al., 1997; Hanno et al., 2011). The value of urine cytology needs to be weighed against the emotional distress that could result from the frequently encountered false-positive result (Davis et al., 2012). Nevertheless, the examination should be considered in the face of clinical factors such as smoking history, age over 40 years, and irritative voiding symptoms.

Box 57.2

Highlights of Clinical Evaluation for the Pelvic Pain Patient

History

General thorough medical history emphasizing the following:

1. Location of pelvic pain and relationship to bladder filling and emptying
2. Presence/absence of initiating event for pain
3. Duration, quality, and radiation of pain
4. Presence/absence of regional pain (i.e., penile, urethral [dysuria?], vulvar, perineal, perianal, testicular, inguinal, coccygeal)
5. Presence or absence of voiding and/or bowel dysfunction
6. Relationship of pain to menstrual cycle
7. Presence/absence of sexual pain (i.e., pain associated with ejaculation, orgasm, entry, and/or deep dyspareunia)
8. Factors that trigger or decrease pain
9. Response to previous therapies
10. History of urologic/gastroenterologic, gynecologic/neurologic/rheumatic disease
11. Previous bladder/pelvic surgery
12. Previous urinary tract infection
13. Previous pelvic irradiation
14. Autoimmune diseases
15. Associated syndromes (irritable bowel, fibromyalgia, chronic fatigue)

Physical Examination

Physical examination emphasizing the following:

1. Abdominal examination: identification of tender anterior abdominal wall musculature, hernias, abdominal distention (tympany), bladder distention, suprapubic tenderness
2. Females: vaginal examination with inspection for abnormal discharge, vulvar dermatoses (i.e., introital mucosal atrophy, lichen sclerosus); pain mapping of vulvar region with Q-tip; one-digit vaginal palpation to identify tenderness or other abnormalities of the bladder, bladder neck, and/or urethra; evaluation for tenderness, hypertonicity, or trigger points of pelvic floor and obturator internus muscles

Males: digital rectal examination with pain mapping of the scrotal-anal region; evaluation for tenderness, hypertonicity, or trigger points of anal sphincter, pelvic floor, and obturator internus muscles

Laboratory Testing

1. Urinalysis
2. Urine culture
3. Urine cytology in risk groups

Symptom Evaluation

1. Voiding diary
2. Visual analog scale for pain
3. Symptom score (i.e., O'Leary-Sant symptom and problem index, University of Wisconsin IC Scale, Pelvic Pain and Urgency/Frequency questionnaire [PUF], Genitourinary Pain Index [GUPI], male or female version, Bladder Pain/Interstitial Cystitis Symptom Score [BPIC-SS])

Other Evaluations

1. Urodynamics (optional)
2. Cystoscopy with or without hydrodistention under anesthesia (Optional. The value of hydrodistention is controversial as indicated in the text.)
3. Bladder biopsy if bladder lesion identified

Modified from Hanno P, Lin AT, Nordling J, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, et al., eds. *Incontinence*. Paris: Health

Publications Limited; 2009:1459–1518.

Difficulties of diagnosis are multiplied by the overlap of other visceral pain syndromes such as male CPPS (Forrest and Schmidt, 2004; Hakenberg and Wirth, 2002). As mentioned earlier in this chapter, similarities between these groups of patients are so striking that they are currently being studied collectively under the rubric of UCPPS by the MAPP Network (Clemens et al., 2015).

Although a table of common confusable disorders is provided (see Table 57.5), two confusable conditions bear special mention as they are likely to be encountered more frequently by the urologic community over the next several years.

Ketamine Cystitis

Ketamine, an NMDA receptor antagonist, is an anesthetic agent and newly popularized treatment for depression that when used recreationally may produce a clinical picture indistinguishable from IC/BPS (Chen et al., 2018; Gauney et al., 2016). Ketamine's rise in popularity as a recreational “club” drug (with street names including “special K,” “super K,” “super acid,” “kate,” “cat valium,” “ket,” ‘ ‘keller,” and “vitamin K”) includes its rapid onset and short duration of action **(**Smith et al., 2002). Ketamine also produces a “dissociative anesthesia” that may be characterized as an unconscious, trancelike state with profound analgesia (Sinner and Graf, 2008). Although ketamine's recreational use appears to have initially blossomed in Asia, abuse has since spread internationally. In 2015, an estimated 2.3 million people in the United States older than 12 years of age were reported to have abused ketamine, with 200,000 having used it within the previous year (National Institute on Drug Abuse, 2015). In a survey of 1900 New York City club-frequenting adults 18 to 29 years of age, 21% admitted to ketamine use, with slightly higher usage by men (Kelly et al., 2006). Mounting evidence suggests ketamine and/or its urine metabolites (e.g., hydroquinone), may be responsible for many of the pathologic and clinical manifestations of this condition (Baker et al., 2016; Misra, 2018). Specific pathologies that have been identified include bladder barrier dysfunction, neurogenic inflammation, immunoglobulin-E–mediated inflammation, overexpression of carcinogenic genes, enhanced apoptosis, and nitric oxide synthase–mediated inflammation (Jhang et al., 2015). The severity of ketamine cystitis’ inflammatory effects appear to be related to the duration of abuse (Gauney et al., 2016; Mak et al., 2011). Early presentation may manifest as only LUTS. Progression of disease is typified by additional complaints including dysuria, worsening frequency, gross hematuria, and pelvic pain. Further ketamine use may produce gross inflammatory changes similar in appearance but usually more widespread than HLs. These inflammatory changes, left unchecked, may result in irreversible bladder wall fibrosis, upper urinary tract changes, and renal dysfunction (Chen et al., 2011; Middela and Pearce, 2011). Successful management of ketamine cystitis begins with early identification and the cessation of ketamine abuse, the latter being the most important and challenging part of care. Hence, we cannot stress enough the importance of rehabilitation in this patient population. **Although ketamine abuse may be seen at any age, the clinician should be especially wary of the young patient who presents with a clinical picture of IC/BPS with visible inflammation of the bladder wall.**

High-Tone Pelvic Floor Dysfunction

HTPFD is commonly identified in patients with urologic, gynecologic, and colorectal pain syndromes (Kuo et al., 2015). Symptoms associated with HTPFD often include pelvic pressure, persistent urgency, the sensation of incomplete bladder emptying (in severe cases, poor bladder emptying is identified), urinary hesitancy, constipation, dyspareunia (pain often experienced the next day), and perineal, penile, and ejaculatory pain (Srinivasan et al., 2007). Although not essential for diagnosis, video-urodynamic evaluation suggests that poor relaxation of the external sphincter is common in IC/BPS (Kuo and Kuo, 2018). Examination of the pelvic floor has identified a myofascial trigger point in approximately 78% of IC/BPS patients, with multiple trigger points identified in 68% of individuals (Bassaly et al., 2011).

HTPFD often magnifies the pain of IC/BPS, or it may be the sole cause of symptoms. In either case, it has been our observation that failure to diagnose HTPFD in the presumed IC/BPS patient will commonly lead to a suboptimal response, as treatment strategies differ between the two conditions. **Hallmarks of HTPFD include the presence of hypertonic pelvic and nearby accessory musculature, muscle banding, and myofascial trigger points, the latter being described as tender "knots" in taut muscle band that produce pain** (Bron and Dommerholt, 2012). One should be particularly concerned about the presence of HTPFD in the patient who endorses a history of dysfunctional voiding, bowel disturbances, and sexual pain; the bowel and bladder disturbances often date back to childhood (Doiron et al., 2017). Physical examination should include a detailed palpation of the pelvic floor musculature and adjacent musculature. If HTPFD is suspected, physical therapy evaluation by a pelvic floor specialist is suggested (Polackwich et al., 2015). A multimodal program consisting of physical therapy, behavior modification (avoidance of straining maneuvers, “reverse Kegels,” stress reduction), topical heat application, skeletal muscle relaxants, control of constipation, and even anesthetic or botulinum neurotoxin type A (BTX-A) injections (myofascial trigger point injections) to affected muscles may be helpful to ameliorate symptoms (Moldwin and Fariello, 2013; Halder et al., 2017).

Beyond the History, Physical Examination, and Urine Studies

The Voiding Diary

Baseline information regarding urinary frequency and volumes voided are helpful for diagnostic purposes and to follow patient progress. One 24-hour period with time of void and volume is usually all that is needed (Mazurick and Landis, 2000). Mounting pelvic discomfort with filling typically drives *low-volume urinary frequency*. The voiding pattern may be indistinguishable from other conditions including OAB or other forms of voiding dysfunction. On the other hand, the finding of frequent but high-volume voids that solely occur during the daytime may suggest other diagnoses.

Symptom Scales for Clinical Assessment and Research

A numerical pain rating scale ranging from 0 (no pain) to 10 (worst pain imaginable) is suggested during initial assessment and can be rechecked along the course of therapy. Baseline information including the characteristics of pain/discomfort and voiding difficulties may be captured using a variety of “short form” instruments (eBox 57.3): O'Leary-Sant symptom and problem index (OSSI/OSPI) (O'Leary and Sant, 1997); Genitourinary (male and female version) Pain Index (GUPI) (Clemens et al., 2009a); Bladder Pain/Interstitial Cystitis Symptom Score (BPIC-SS) (Humphrey et al., 2012); Pelvic Pain and Urgency/Frequency questionnaire (PUF) (Parsons et al., 2002a); University of Wisconsin IC Scale (Goin et al., 1998; Keller et al., 1994). From a clinical perspective, each instrument to varying degrees may provide the clinician with a gestalt of the patient's overall clinical condition. For example, the GUPI provides information regarding location of pain, the presence of sexual pain, and effects on QoL. Although no questionnaire has been shown to be of value in definitive diagnosis (Kushner and Moldwin, 2006; Moldwin and Kushner, 2004), more recent instruments such as the GUPI and BPIC-SS have shown enhanced ability to distinguish IC/BPS from other urologic conditions.

eBox 57.3

Clinical Symptom Scales

University of Wisconsin IC Scale (Goin et al., 1998; Keller et al., 1994): Includes seven IC/BPS symptom items. It has not been validated for the diagnosis of IC/BPS but captures severity of symptom expression. This scale addresses some quality-of-life issues, and this is an advantage when such issues are the subject of investigation. Its most attractive aspects are its clinically apparent face validity and its ease of implementation. It is rarely used in current literature.

O'Leary-Sant Symptom and Problem Indices (OSSI/OSPI) (O'Leary and Sant, 1997; O'Leary et al., 1997): Questionnaire that was originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to IC patients and asymptomatic controls. The more commonly used OSSI has three questions related to urgency and frequency and one on bladder-associated pain. Its primary utility has been to assess clinical change over time (Lubeck et al., 2001). Although these problem indices may differentiate between IC/BPS and controls, the instrument was not developed to be used as a screening tool. Additionally, all questions pertain to symptoms “during the past month,” raising concerns of recall bias.

Pelvic Pain and Urgency/Frequency questionnaire (PUF) (Parsons et al., 2002a): The PUF was specifically designed to include questions that directly reflect a wide variety of the symptoms experienced by afflicted patients. One-third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum. The PUF score has been indexed to the results of a potassium sensitivity test (assessment of irritative symptoms and/or pain suggestive of IC/BPS, after intravesical instillation of a dilute KCl solution). A large study using the PUF has concluded that up to 23% of female Americans have IC/BPS (Parsons et al., 2002a). This makes one wary as to the usefulness and face-validity of the PUF for diagnosis (Ito et al., 2003). Irrespective of its role in diagnosis, the PUF does focus on many clinical parameters that affect patients.

Genitourinary Pain Index (GUPI), male and female versions (Clemens et al., 2009a): This validated 9-question instrument (including a numerical pain scale) discriminated between men with chronic prostatitis or interstitial cystitis, those with other symptomatic conditions (dysuria, frequency, chronic cystitis), and those with none of these diagnoses. The GUPI includes clinically relevant questions regarding the location and other characteristics of pain, voiding symptoms, and effects on QoL. GUPI questions relate to symptoms from the past week (rather the past month), thus limiting recall bias.

Bladder Pain/Interstitial Cystitis Symptom Score (BPIC-SS) (Humphrey et al., 2012): This 8-question instrument (one question is a numerical pain rating scale) was validated to better identify moderate to severe IC/BPS patients (as compared with controls and OAB patients) for clinical trials with strong sensitivity (0.72) and specificity (0.86). Its ability to differentiate from OAB is likely because 5 of 8 questions center on pain or pressure. Like the GUPI, this instrument draws on the recollection of symptoms over the past week.

Global Response Assessment (GRA): The GRA has no place in the initial evaluation of the IC/BPS patient. Rather, this tool is a balanced patient self-report on overall response to therapy, developed for NIDDK-sponsored multicenter therapeutic trials (Sant et al., 2003). A one-category change in GRA correlates with a 1.2-point change in the O'Leary-Sant and a 3.1-point change in the University of Wisconsin instruments (Propert et al., 2006).

Urodynamic Evaluation

The primary value of urodynamic studies in the evaluation of IC/BPS is limited to the identification of other functional bladder pathology(ies) that may confound diagnosis and hinder therapeutic progress.

Cystometry in IC/BPS patients typically demonstrates normal detrusor function but a decreased bladder capacity and hypersensitivity. Bladder compliance is normal, as hypersensitivity would prevent the bladder from filling to the point of noncompliance (Siroky, 1994). Pain on bladder filling that reproduces the patient's symptoms is very suggestive of the diagnosis.

Many dispute the need for urodynamic study noting that most patients can be treated successfully based on the clinical presentation. Bladder outlet obstruction is a common occurrence in the female IC/BPS patient, presumably related to pelvic floor dysfunction (Cameron and Gajewski, 2009). The authors suggested that typical symptoms of voiding dysfunction should prompt a course of dedicated therapy and that urodynamic evaluation adds little information to change the course of care.

DO and IC/BPS may coexist in 15% to 19% of patients (Gajewski et al., 1997, Kirkemo et al., 1997). The case for urodynamics to exclude concomitant DO as a cause for irritative voiding symptoms (not pain) is debatable, as empirical therapy can easily be justified as a first-line maneuver. Additionally, medications such as amitriptyline, often used early in the course of care, have anticholinergic properties, which may resolve the issue. Of course, urodynamic evaluation would likely provide useful information for those patients who fail empirical therapy or those who present with a confusing clinical picture (e.g., pain, urgency frequency, and urinary retention). Complex cases may benefit from full video-urodynamic studies (Carlson et al., 2001).

Office Cystoscopy

Current guidelines established by the American Urological Association do not require cystoscopic evaluation in the *routine* management of IC/BPS as visual findings are generally unrevealing. We favor early endoscopy as the finding of a Hunner lesion would direct management in a different (usually more aggressive) direction. **Although the extent of HLs has been correlated to symptom severity and bladder capacity** (Akiyama et al., 2018)**, they cannot be reliably identified on the basis of clinical presentation or urine studies** (Braunstein et al., 2008; Doiron et al., 2016). Experimental data suggest that measurement of increased nitric oxide levels in the bladder can accurately identify those with inflammatory disease, but this has not folded over to routine clinical care (Logadottir et al., 2004). Flexible cystoscopy in the office setting can be accomplished with minimal discomfort and often provides the patient with immediate relief from concerns of bladder cancer. HLs can be identified (Fig. 57.6). Narrow-band imaging may enhance the identification of subtle lesions during the office procedure (Kajiwara et al., 2014). Although perhaps not as sophisticated as standard urodynamic evaluation, bladder filling during the examination allows an assessment of bladder capacity (best obtained with the voiding diary) and reproduction of pain with bladder filling. Specific sites of hyperalgesia such as the bladder neck can also be identified using the tip of the cystoscope as an examining finger. On a final note, office cystoscopy offers an opportunity to drain the bladder, then to introduce an anesthetic (i.e., alkalinized) lidocaine. Significant relief of pain after this “anesthetic challenge” suggests a bladder origin to pain. Lack of response does not exclude a diagnosis of IC/BPS (Cox et al., 2016).

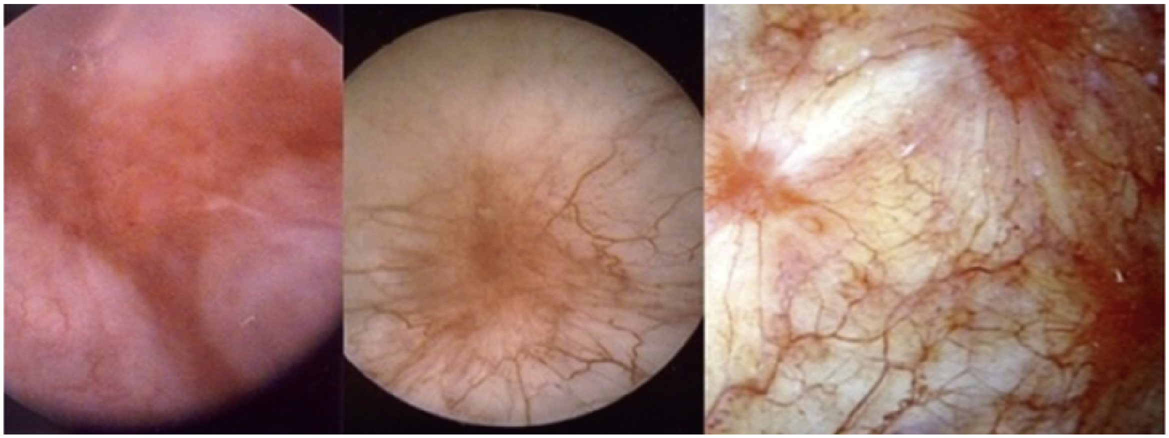


FIG. 57.6 Varied appearances of Hunner lesions identified on routine cystoscopic examination. Note the stellate appearance. Bleeding and disruption of the lesions usually occurs centrally with bladder distention. Fibrous bridging between lesions may occur, which further restricts bladder capacity.

Cystoscopy With Hydrodistention and Biopsy

Long before it was considered a diagnostic tool, cystoscopy with hydrodistention (CHD) was used as a therapeutic modality for IC/BPS (Bumpus, 1930). **CHD under anesthesia allows for sufficient distention of the bladder to afford visualization of submucosal pinpoint petechial hemorrhages, termed *glomerulations* (Fig. 57.7). After filling to 80 cm of water pressure for 1 to 2 minutes, the bladder is drained and refilled. The terminal portion of the effluent is often blood-tinged. Reinspection will reveal the glomerulations that develop throughout the bladder after distention and** are not usually seen during examination without anesthesia (Nigro et al., 1997b).

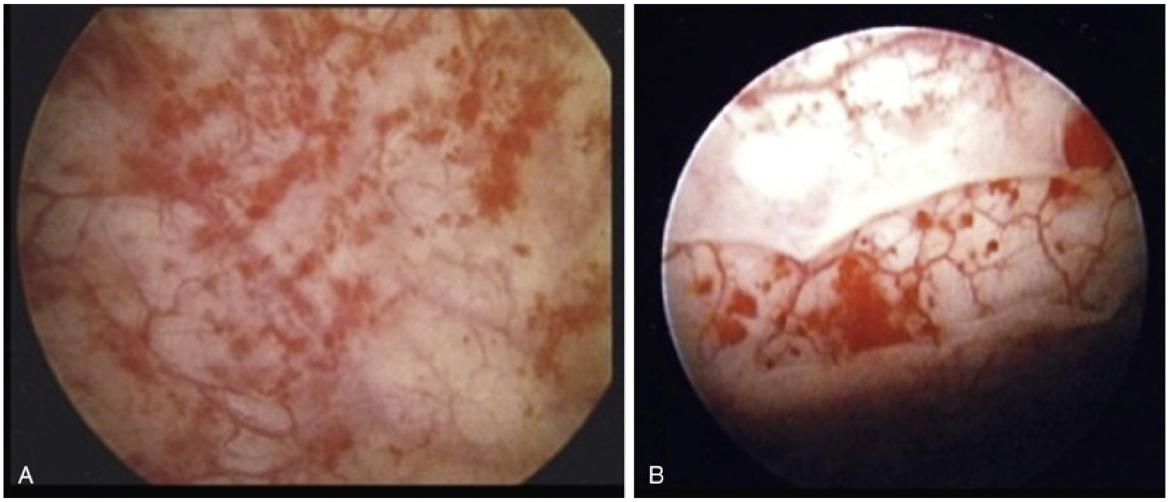

FIG. 57.7 (A) Typical appearance of glomerulations after bladder distention in a patient with interstitial cystitis/bladder pain syndrome without a Hunner lesion. (B) Mucosal tears that frequently develop during hydrodistention, often near the bladder neck (note the submucosal glomerulations).

Glomerulations are not specific for IC/BPS (Erickson, 1995; Waxman et al., 1998), and only when seen in conjunction with the clinical criteria of pain and frequency can the finding of glomerulations be viewed as potentially significant. **Glomerulations can be seen after radiation therapy, in patients with carcinoma, after exposure to toxic chemicals or chemotherapeutic agents, and often in patients on dialysis or after urinary diversion when the bladder has not filled for prolonged periods.** They have been reported in the majority of men with prostate pain syndromes, begging the question as to whether CPPS in men is closely linked with IC (Berger et al., 1998). They are observed in up to 20% of men undergoing transurethral prostatectomy for LUTS (Furuya et al., 2007). We have speculated that they may simply reflect the response of the bladder to distention after a prolonged period of chronic underfilling because of sensory urgency, rather than resulting from a primary pathologic process.

Further confusion arises when the patient demonstrates the symptoms of IC/BPS but the cystoscopic findings under anesthesia are completely normal. This occurred in 8.7% of patients undergoing CHD entered into the IC database (Messing et al., 1997). Awad et al. recognized this entity soon after the NIDDK research criteria had been described. They reported on a series of patients in whom the symptomatology, urodynamic evaluation findings, histology, and response to therapy were identical to IC/BPS but in whom findings on CHD were normal. It was termed *idiopathic reduced bladder storage* (Awad et al., 1992). Clinical, urodynamic, and cystoscopic data strongly suggest that the presence of glomerulations is not selecting out a meaningful difference in patients with symptoms of IC/BPS (Al Hadithi et al., 2002; Wennevik et al., 2016).

The presence of glomerulations on cystoscopy with hydrodistention may identify a group of patients with worse daytime frequency and nocturia, lower mean voiding volumes, and lower bladder capacity under anesthesia, but does not have any relationship to biopsy findings, bladder pain, or urgency (Boudry et al., 2013; Erickson et al., 2005). **A low bladder capacity at the time of hydrodistention (anesthetic bladder capacity) may represent a distinct clinical phenotype, having higher symptom scores and fewer reports of depression and IBS, essentially a more bladder-centric patient picture** (Walker et al., 2017).

Although hydrodistention has been commonly employed to provoke the appearance of an HL, this practice has been recently questioned (Nickel and Moldwin, 2018). As noted in the preceding section, office cystoscopy can easily identify these lesions. Furthermore, the finding of a focal bladder lesion that can only be identified on the basis of distention of the bladder well beyond its normal functional capacity suggests that this group may represent a different place in the spectrum of disease or a different phenotype altogether.

Despite a possible role to phenotype patients, the value of cystoscopy with hydrodistention for diagnosis appears to be clinically limited. Bladder biopsy is indicated only if necessary to rule out other disorders that might be suggested by the cystoscopic appearance. One common indication for biopsy is to differentiate an HL from carcinoma in situ.

The Search for a Marker

Development of a specific marker for a symptom complex that may coexist with other regional or widespread pain syndromes is daunting and probably unrealistic. Rather, we hope that biomarker development will help stratify patients into phenotypic subgroups that may share similar pathology and response to therapy. The markers themselves may also represent therapeutic targets for future drug development. Markers that have been studied fall into groups including: inflammatory mediators, proteoglycans, urinary hexosamines and GAG, proliferative factors, nitric oxide, urothelial proinflammatory gene expression, and viruses (Grigorescu et al., 2016).

One of the earliest studied markers for diagnosis of IC/BPS was the mast cell count. Biopsies were routinely obtained (at the time of hydrodistention) and analyzed in a standardized fashion with greater than 27 mast cells per cubic millimeter being indicative of mastocytosis (Larsen et al., 2008). Studies regarding the mast cell count's role for IC/BPS diagnosis were conflicting, and no study to date has associated mast cell counts with response to therapy (e.g., antihistamines). Given these factors, the use of mast cell criteria is not recommended outside the realm of research (Christmas and Rode, 1991; Dundore et al., 1996; Feltis et al., 1987; Hanno et al., 1991; Holm-Bentzen et al., 1987a; Kastrup et al., 1983; Lynes et al., 1987; Moore et al., 1992). Methylhistamine, a histamine metabolite found in the urine and thought to reflect mast cell activation, was not associated with symptom scores, response to bladder distention, cystoscopic findings, or bladder biopsy features including mast cell determination by tryptase staining (Erickson et al., 2004).

Multiple urinary markers have been investigated (Erickson, 2001, Erickson et al., 2002), including eosinophil cationic protein (Lose et al., 1987), GAG excretion (Hurst et al., 1993), and urinary histamine and methylhistamine (El Mansoury et al., 1994). Proposals for measuring smooth muscle isoactin expression (Rivas et al., 1997) and urinary levels of neurotrophin-3, nerve growth factor, glial cell line–derived neurotrophic factor, and tryptase (Okragly et al., 1999) have been suggested. Low levels of GP51, a urinary glycoprotein with a molecular weight of 5 kDa, have been documented in IC patients compared with normal controls and patients with other urinary tract disease (Byrne et al., 1999), suggesting surface mucin aberrations.

The measurement of elevated nitric oxide levels in air instilled and incubated in the bladder has been proposed for office screening (Ehrén et al., 1999; Lundberg et al., 1996). Increased levels of endogenously formed nitric oxide in patients with IC correspond to increased iNOS mRNA expression and protein levels in these patients. Furthermore, iNOS was found to be localized to the urothelium, but it was also found in macrophages in the bladder mucosa (Koskela et al., 2008). The simple technique allows for discrimination of ulcer from non-HL disease (Logadottir et al., 2004) and may provide an objective measure of treatment response (Hosseini et al., 2004).

Urinary macrophage inhibitory factor (MIF) levels in female patients with IC/BPS and HLs are approximately fivefold higher than MIF levels in female non-IC/BPS patients or IC/BPS patients without HLs. Urinary MIF was also elevated in males with other forms of bladder inflammation (bacterial and radiation cystitis), indicating that, although a good marker to detect inflammation, MIF was not specific for the presence of IC/BPS with HLs. Nevertheless, the assay may better select out those patients who would benefit from early cystoscopic evaluation, and it may pose as a target for future therapies for IC/BPS and other inflammation-based bladder diseases (Vera et al., 2018).

Patients with HLs were found to have a 5-fold to 20-fold increase in the chemokines CXCL-10 and CXCL-1, interleukin-6, and nerve growth factor when compared with BPS patients without HLs (Tyagi et al., 2012). Different expression patterns of the genes involved in pronociceptive inflammatory reactions suggest distinct pathophysiologies for HL patients compared with patients with IC/BPS without HLs (Homma et al., 2013).

Of all biomarkers analyzed for the diagnosis of IC/BPS to date, none has shown higher sensitivity (95%) and specificity (95%) to differentiate IC/BPS from healthy controls than urinary antiproliferative factor (APF), a “frizzled 8 protein” that belongs to a family of proteins that appear to have a role in the development of nerve tissues, skin, and the lining of organs (Keay et al., 2004b). APF is known to inhibit the proliferation of urothelial cells in vitro and is associated with decreased production of heparin-binding epidermal growth factor–like growth factor (HB-EGF) (Keay et al., 2000). APF activity was related to increased production of epidermal growth factor (EGF), insulin-like growth factor-1, and insulin-like growth factor–binding protein-3 by the bladder cells from IC/BPS patients but not by the cells from healthy bladders. Studies of IC/BPS patients and asymptomatic controls showed **urine levels of APF, HB-EGF, and EGF to reliably separate IC/BPS from controls** (Erickson et al., 2002; Keay et al., 2001b). Despite current concepts of overlapping pathologies between men with IC/BPS and CP/CPPS, APF levels in the urine were found to discriminate between men with IC/BPS versus those with CPPS or nonbacterial prostatitis (Keay et al., 2004a). Data regarding the reproducibility of APF and any practical clinical uses are lacking.

Uroplakin III-delta 4 is a potential marker for identifying IC/BPS with HLs (Zeng et al., 2007). The feasibility of diagnosing IC/BPS in humans and domestic cats from the spectra of dried serum films (DSFs) using infrared microspectroscopy has been reported (Rubio-Diaz et al., 2009).

Recent studies through the MAPP Network have shown female IC/BPS patients to exhibit a heightened inflammatory response compared with healthy controls as identified through stimulation of Toll-like receptor 2 (TLR2) and

TLR4 in patient-derived peripheral blood mononuclear cells (PBMCs). A TLR4 inflammation score correlated strongest for pain frequency and intensity (Schrepf et al., 2014). A one standard deviation increase in TLR4 inflammatory response was associated with a 1.59 greater likelihood of extrapelvic pain. Furthermore, patients with comorbid syndromes had higher inflammatory responses to TLR4 stimulation in PBMCs. The TLR4 response was also associated with low-pressure pain thresholds (Schrepf et al., 2015). TLR7 is associated with SLE and SS, two inflammatory conditions that are more frequently identified in the IC/BPS population. Ichihara et al. identified increased *TLR7* gene expression and TLR7 immunoreactive cells in the bladder biopsies of IC/BPS patients with HLs compared with control specimens, further suggesting that these conditions may represent two different pathologic states (Ichihara et al., 2017). Differentiation of IC/BPS with HLs from other forms of cystitis is crucial for future investigations.

Potassium Chloride Test

The intravesical KCl challenge has been described as an aid to diagnose IC/BPS (Parsons et al., 1998). The test essentially compares the sensory nerve provocative ability of sodium versus potassium using a 0.4-M KCl solution. Pain and provocation of symptoms constitutes a positive test result. Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients or hypersensitivity of the sensory nerves is unclear. When first described, the KCl test was thought to help identify the IC/BPS patient without the need for cystoscopy and hydrodistention under anesthesia. Of course, as our diagnostic paradigm has shifted to one that is symptom-based, the need for a provocative test, one that can result in a great deal of patient discomfort, has waned. Accordingly, **used as a diagnostic test for IC/BPS, the KCl test is not recommended.** Interestingly, a negative KCl test will be seen in up to 25% of patients meeting strict NIDDK research criteria (suggesting a lack of sensitivity in a group of patients that would more likely respond). Specificity has also been of concern as a 36% false-positive rate was identified in asymptomatic men (Yilmaz et al., 2004) and a 33% positive rate in a fixed population of Turkish textile workers (Sahinkanat et al., 2008). Sensitivity to the KCl solution may also be present in 25% of patients with OAB. Virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive (Parsons et al., 1994b, 1998). The results with chronic prostatitis and CPPS in men are variable, but 50% to 84% of men have been reported to test positive (Parsons and Albo, 2002; Parsons et al., 2005; Yilmaz et al., 2004). In women with pelvic pain, the results are similar (Parsons et al., 2002b), and, based on these findings, Parsons has expressed the view that IC/BPS may affect over 20% of the female population of the United States (Parsons et al., 2002a). Another way to interpret the findings would be that the KCl test is very nonspecific, missing a significant number of IC/BPS patients and overdiagnosing much of the population.

Key Points: Diagnosis

- IC/BPS remains a diagnosis of exclusion in patients who meet the symptomatic criteria for diagnosis.
- The identification of confusable conditions that may mimic bladder-based pain or present as additional pain generators (e.g., HTPFD) is essential for a successful therapeutic outcome.
- Although cystoscopy is not mandatory for diagnosis, a flexible office cystoscopy may be considered early in the course of care to exclude the presence of HLs.
- Cystoscopy and upper tract imaging are mandatory in patients with hematuria who have not been previously evaluated for this finding.
- Urodynamics are optional and usually reserved for complex cases.
- There are no commonly available laboratory markers that substantially contribute to diagnosis.

Treatment of Interstitial Cystitis/Bladder Pain Syndrome

Before embarking on therapy for the IC/BPS patient, the clinician must first be cognizant that there is no "home run" therapy available that will apply to all patients, most certainly a result of heterogeneity of the population. This leaves a trial-and-error approach to treatment that can quickly breed frustration for the patient. Much of this frustration and perhaps secondary depression can be mitigated to a significant degree by establishing treatment goals and realistic expectations, moving forward as partners in management.
